can also learn to recognize spoken English and may modify their own vocal production as a result of enculturation (e.g., Heimbauer et al. 2011; Savage-Rumbaugh et al. 1993; Taglialatela et al. 2003). The methods and apparatus used to provide language training to apes are also transformative when applied to human youth with language impairments (e.g., Ronski and Sevcik 1991), and there is evidence that techniques developed for nonhuman primates may be similarly effective as interventions with children for other cognitive competencies (e.g., Rueda et al. 2005). Nonhuman primates can also learn symbols that represent quantities, use the symbols to count, perform simple combinatorial operations, and judge quantities using analog representations (e.g., Beran et al. 2007; Rumbaugh 2013). The animals show other evidence of rule-like, relational learning on a variety of tasks, as well as memory performance that may suggest mental time travel to the past (i.e., episodic-like what-where-when memory) or the future (i.e., prospective memory; Beran et al. 2016). Such findings underscore the continuity of cognitive competencies; however, interesting species differences also appear (e.g., Flemming et al. 2007; Pr  t  t et al. 2016; Rumbaugh and Washburn 2003; Smith et al. 2016b). For example, humans, chimpanzees, and macaques show robust evidence of meta-cognitive monitoring of subjective cues, whereas such evidence has been elusive from capuchin monkeys (e.g., Smith et al. 2016b). Phenotypic individual or species differences in behavior may be predicted from variations in genotype, brain structure, activation (e.g., Hecht et al. 2017; Latzman et al. 2016). The importance of social variables is also revealed by the primates' performance on tests of inequity aversion, prosociality, cooperation, social recognition, deception, and economic decision making (e.g., Hall and Brosnan 2016; Talbot et al. 2016). By comparing performance across primate species, across development, and across experience, the competition between stimulus control of behavior and cognitive control is brought into focus, as are the factors that allow organisms to be more self-directed and purposive in behavior (e.g., Beran et al. 2014, 2016).

LRC scientists have also authored or edited 20 books, including *Ape Language: From*

*Conditioned Response to Symbol* (Savage-Rumbaugh 1986); *Biological and Behavioral Determinants of Language Development* (Krasnegor et al. 2013); *Primate Laterality* (Ward and Hopkins 1993); *Communicating Meaning* (Velichkovsky and Rumbaugh 1996); *Breaking the Speech Barrier* (Ronski and Sevcik 1996); *Kanzi: The Ape at the Brink of the Human Mind* (Savage-Rumbaugh and Lewin 1994); *Apes, Language, and the Human Mind* (Savage-Rumbaugh et al. 1998); *Intelligence of Apes and Other Rational Beings* (Rumbaugh and Washburn 2003); *Animal Bodies, Human Minds* (Hillix and Rumbaugh 2004); *Educating the Human Brain* (Posner and Rothbart 2007); *Primate Perspectives on Behavior and Cognition* (Washburn 2006); *The Evolution of Hemispheric Specialization in Primates* (Hopkins 2007); *Animal Acoustic Communication* (Hopp et al. 2012); *Foundations of Metacognition* (Beran et al. 2012); *Number Without Language: Comparative Psychology and the Evolution of Numerical Cognition* (Agrillo and Beran 2013); and *With Apes in Mind* (Rumbaugh 2013). Many of the scientific contributions discussed above are detailed in these publications.

The LRC has also been active in disseminating research findings through electronic media, including video documentary of methods and results, as well as interviews or brief features on websites, television, or radio programs. Noteworthy contributions include *The Amazing Apes* (1977) featuring Lana and her lexigram use; *Ape Language: From Conditioned Response to Symbol* (1986), with documentary footage of Sherman and Austin to accompany the Savage-Rumbaugh (1986) book by the same name; *Lana Chimpanzee Learns to Count by "Numath"* (Rumbaugh et al. 1989) on numerical cognition research; and *Bonobo People* (1993), including footage filmed by NHK on the research with Kanzi and his family of bonobos. Similarly, public exhibits on LRC research have been included in the American Psychological Association's centennial celebration traveling exhibit and in the American Museum of Natural History in New York.

LRC scientists have also made important methodological contributions to comparative

psychology. From apparatus innovations like the computerized language keyboard and the joystick-based computer-test system to specific testing paradigms (both automated and manual), many of the methods developed at the LRC have been adopted for comparative research at other research facilities. For example, the innovative training procedure and apparatus configuration that allowed rhesus monkeys to respond to computer-generated stimuli via joystick manipulation (Rumbaugh et al. 1989) were exported to dozens of laboratories. This computerized test system has become a standard testing paradigm for comparative research, and has been shown to provide environmental enrichment to nonhuman primates, addressing three of a (human or non-human) primate's basic dimensions of psychological well-being: challenge, control, and comfort (Washburn 2015). Given recent refinements of the paradigm for the testing of socially housed animals (Fagot and Bonté 2010; Gazes et al. 2012), the system is also compatible with the fourth dimension of well-being: companionship.

## Summary

The LRC is a facility with uncommon research and training resources. The LRC is also a resident colony of special primates with unique skills and experiences. The LRC is a team of creative and collaborative scientists who are excited about the challenges of understanding primate (including human) minds and behavior. It is a center with a rich past and with a promising future. At a time when science is becoming increasingly collaborative, increasingly interdisciplinary, increasingly about working together, the LRC embraces its partnership with nonhuman primates as it pursues its mission: "so that together we might learn."

## Gerald S. Wilkinson

Gerald G. Carter

Smithsonian Tropical Research Institute, Balboa, Ancón, Republic of Panama

Gerald Wilkinson is a behavioral ecologist and evolutionary geneticist who has spent his career testing assumptions and predictions of highly debated evolutionary theories involving sexual selection and cooperation. He is best known for his work on cooperation in bats and sexual selection and meiotic drive in stalk-eyed flies.

Wilkinson was born in 1955 in San Francisco and grew up near Sacramento California. As a kid, he chased jack rabbits and kept pet reptiles he caught in the fields near his home. He fostered his naturalist curiosity further in the boy scouts and became an avid birder, but always “found it more interesting to watch what the birds were doing, than to simply count seeing a rare bird.” As an undergraduate at UC Davis, he took a course on primate behavior taught by Peter

Rodman, who later allowed Wilkinson to be the sole undergraduate in his graduate student seminar, which covered E. O. Wilson's newly published book *Sociobiology*. Wilkinson enjoyed reading, discussing, and debating the topics of the book. Less than a decade later, he himself would make substantial contributions to this new field.

While an undergraduate, Wilkinson conducted a field study with a classmate to see if industrial dumping of tomato waste increased rodent densities and hence raptor density, leading to his first publication. A few years later, he and another classmate also completed a study on predation and group size in cliff swallows.

Wilkinson also took a methods course by Rodman where he learned how to perform and analyze observational data by studying bonnet macaques at the UC Davis primate center. He would later use these methods in his classic PhD work on vampire bats. Rodman recognized Wilkinson's motivation and talent and suggested he pursue a PhD with behavioral biologists Jack Bradbury and Sandra Vehrencamp at UC San Diego, which he did. During mandatory lab rotations, he developed a method to catch roadrunners for radio-tagging, created an optimal foraging model for sea otters, wrote four short research proposals, and learned enzyme electrophoresis – another method he would employ during his study of vampire bats.

Wilkinson's PhD advisor, Jack Bradbury, was trained by Donald Griffin, who discovered echolocation in bats. By the end of the 1970s, Bradbury was the leading expert on bat sociality. At this time, inclusive fitness theory was inspiring biologists to use newly developed genetic techniques to look at the effects of kinship on cooperative behavior. At a scientific meeting, Uwe Schmidt, the world's leading expert on vampire bat behavior, described regurgitated food-sharing behavior in his captive colony of vampire bats. Bradbury wrote Wilkinson, then stationed in Costa Rica, and suggested that he study this behavior in the wild.

In Costa Rica, Wilkinson initially began a project looking at a common nectar-feeding bat, but this species would abandon their roosts after he marked them with wing bands, so he was eager to consider an alternative. He individually

marked vampire bats with bands and found he could continue observing them after slowly habituating them to small amounts of light. Wilkinson and his team of field assistants spent over 400 h observing the bats within their roosts. This process involved wearing a protective respirator while lying inside a cockroach-infested hollow tree full of vampire bat feces. Regardless, Wilkinson enjoyed his work and became quite fond of the vampires, which often groomed each other, like primates.

His findings, based on a 5-year study, including 3 years of intense fieldwork, showed that wild female vampire bats regurgitate blood to help not only their own offspring but also hungry kin and nonkin adult females of high association. Wilkinson then showed experimentally that food donations among unrelated adults were predicted by past reciprocal donations. When Wilkinson returned to the USA, the two explanations for altruism in animals were that animals help individuals based on genetic relatedness, (i.e., kin selection) or that they helped based on past experience of helping (i.e., reciprocal altruism). In the food-sharing vampire bats, Wilkinson found evidence supporting both hypotheses. A surge of interest in reciprocal altruism came from an evolutionary game theory paper (Axelrod and Hamilton 1981) showing that a strategy of reciprocal helping (“tit for tat”) could outcompete selfish strategies even under conditions that made cooperation nearly impossible (“the prisoner's dilemma”). When it was published, Wilkinson's report on food sharing in vampire bats was one of the most convincing cases for such reciprocity in nature and was highlighted in textbooks, magazines, and popular science books (e.g., the second edition of *The Selfish Gene* by Richard Dawkins). With more than 900 citations as of 2016, Wilkinson's 1984 paper on reciprocal food sharing in vampire bats is his most often-cited publication.

Later as a professor at University of Maryland, Wilkinson advised several students who studied social behavior and social learning in bats, often in collaboration with his University of Maryland colleague, Cindy Moss. One of the lab's more fascinating lines of research, led by two PhD students, first Jenny Boughman and later Kisi

Bohn, was that neotropical greater spear-nosed bats, which live in unrelated female groups, produce a group-specific “screech call” that is consistent across group members (reviewed by Wilkinson et al. 2016). These group signature calls are used for maintaining contact and are learned over time. Infants, however, make an individually distinct “isolation call” that is important because the helpless pups sometimes fall to the floor of caves where females from other groups will try and kill them. Astonishingly, unrelated females from the same group will defend them, a cooperative behavior which remains to be fully explained (Bohn et al. 2009; Wilkinson et al. 2016).

Since his PhD, the main focus of Wilkinson’s work, however, shifted from bats to stalk-eyed flies. He sought to test some of the underlying assumptions of genetic models that provide the foundation for much social evolution theory, and this would require developing skills and techniques for studying evolution more directly and rigorously in organisms that were more tractable than bats. As a postdoc at the University of Sussex and then at the University of Edinburgh, he began experiments that addressed two influential theory papers on sexual selection (Lande 1981, Kirkpatrick 1982) that described the genetic conditions leading to either an equilibrium between sexual and natural selection or a state of positive feedback, e.g., Fisherian runaway sexual selection. A key assumption of the first condition is that natural and sexual selection act in opposite directions. Wilkinson first confirmed this in fruit flies, but he really wanted a model organism with more explicit female choice.

Stalk-eyed flies seemed perfect. Their eyes are mounted on the ends of long stalks, which are dramatically larger in males, and are used to attract females and compete with males. Wilkinson heard from faculty member Arthur Ewing about stalk-eyed flies he had seen on Mount Kenya during a recent holiday. Wilkinson (2001) described his excited reaction:

Within a month, I had booked a cheap flight from London to Nairobi. The day after I arrived, just as he had described, I found stalk-eyed flies in several streams in the forests on Mount Kenya.

He brought flies back to Scotland and bred them in the lab. However, during his second postdoc at UC Boulder studying behavioral genetics and communal nursing in mice, he was unable to secure the permits to bring his stalk-eyed flies to Colorado.

In 1987, Wilkinson joined the faculty at University of Maryland, where he setup a lab to study bats in the field and to conduct artificial selection experiments with stalk-eyed flies in the lab. There, he tested a key assumption of sexual selection models: a genetic correlation between the male trait and the female preference. If such a correlation exists, then selecting on the male trait should lead to changes in female preferences in those genetic lineages. The Wilkinson lab selected males on the ratio of eyespan to body length for 2 years (or 13 generations). Then he tested female preference. As expected, females from short-stalk male lines preferred short-stalk males, whereas females from long-stalk male lines preferred long-stalk males.

In the 1990s, Wilkinson teamed up with Rick Baker (then a graduate student at Yale) to study the evolution of sexual dimorphism in stalk-eyed flies. He also conducted a large study with six species of stalk-eyed flies to measure the magnitude of change in genetic variation and covariation for traits that were either under natural or sexual selection to complement his ongoing selection experiment, which he wanted to use to directly measure changes in genetic variation. While counting the numbers of male and female offspring from half-sib families in each line, he stumbled across something astonishing.

Male flies from the short-stalk lines produced primarily female offspring, while male flies from the long stalk lines produced more male offspring. Eventually Wilkinson’s lab found that this was due to a process called sex chromosome meiotic drive, whereby one of the sex chromosomes is transmitted more often. For example, meiotic drive can lead to all of one’s offspring being 100% female. The “driving” X chromosome is a selfish genetic element that spreads itself at the expense of the other genes and the fitness of the individual as a whole. Genes on the other chromosomes are therefore selected to suppress drive. The result is an evolutionary battle of genes within the genome.

Wilkinson's lab detected this intragenomic conflict in the stalk-eyed flies he brought from Southeast Asia. By decreasing eyespan, the lab had increased the frequency of the drive X chromosome, which led to more female offspring. He faced an astonishing hypothesis: Did the females choose long-stalked males to increase their fitness by producing more males?

Indeed, a combination of models and experiments supported the notion that male stalk length advertises the presence or absence of a drive X chromosome and that meiotic drive could accelerate the process of sexual selection (Wilkinson et al. 1998). Over the next decade, the Wilkinson lab showed that the genes influencing stalk length and those causing sex chromosome meiotic drive were linked. They discovered that stalk-eyed flies possess a "neo-X" chromosome and they determined that many genes have duplicated and moved on and off of this chromosome over evolutionary time. By sequencing the genome for a stalk-eyed fly, they searched for gene duplications and sex-specific changes in gene expression across different tissues for over a dozen different species of flies. These studies continue and are providing insight into the origin and evolution of sex chromosomes.

A unifying theme of Wilkinson's work is understanding the factors that promote or prevent cooperation. He points out that meiotic drive is really a lack of cooperation among chromosomes, much like cancer is a lack of cooperation between cells in the body. Is meiotic drive a consequence of the genome's defense system not working properly? Wilkinson's work continues to ask such questions.

In reflecting on his scientific career, Wilkinson notes that some of his most influential discoveries came through recognizing something surprising in his data that were theoretically interesting. There's a lesson here: continuously check your data, and know the current theory and literature well enough to tell when a strange result is interesting. As Wilkinson (2001) explained, "future advances in the field will depend on discovering behavioral patterns that fail to conform to conventional theories. My best advice, therefore, is to be alert for the unexpected. Such discoveries may

well turn out to be more important than any preconceived ideas under examination."

## Definition

Gestalt psychology was a school of thought originating in the early twentieth century that defended a molar view of perception. According to Gestalt principles, perception involves an active organization of stimuli that takes place within schemes of meanings. A widespread contribution of gestalt theory was to synthesize in laws the ways in which perceptual information tends to be grouped through conceptualization.

## Introduction

Essentially, Gestalt psychology defined perception as a process that organized the world of objects. According to gestalt theorists, this process is led by meanings and not by the adding of one part to others. The objective of gestalt principles was to demonstrate that perception is not simply an accumulation of information.

If we search the etymological sense of the term, Gestalt is a German noun that means form, or figure. Additionally, Gestalten is a verb that means organize, configure, or restructure. Gestalt psychology postulates an innate origin of certain categories that give rise to the schemas in which we perceive. The theory claims that perception does not come from emptiness but, as Kant stated (Oviedo 2004), perception goes beyond the literal data and builds global phenomena. Classic examples of gestalt perception include well-known optical illusions in which a visual pattern can be perceived according to multiple conceptualizations. An example of this is the Necker cube (see Fig. 1), in which two different cubes may be perceived, depending on the point where the deeper perspective is fixated. To gestalt theorists, this is proof that a molecular definition of perception is not possible. That is, the object perceived comes from a qualitative organization of stimulus characteristics. Depending on the frame of perception, object perception can change without modifying the composition or arrangement of its features. Another well-known example, characteristic of gestalt analysis, is the image

**Gestalt, Fig. 1** Necker cube. The perspective of the 3D cube can change depending on the fixation point

**Gestalt, Fig. 2** Older and young women illusion (Adapted from Boring 1930)

of the young and the older woman and its numerous versions (see Fig. 2).

In contrast to the atomistic perspective of cognition, which claims additive summation of discrete stimuli as the main function of perception (Katz 1945), Gestalt psychology suggests that perception involves forming hypotheses about stimuli in the world. Historically, taking into account the physiological trends up until the early twentieth century, Gestalt explanations in terms of meanings, wholes, and interpretations of stimuli seemed revolutionary. The Gestalt theory contrasted with the historical period in which it emerged because of its molar level of explanation, in opposition with the elementary point of view. For instance, Katz (1945) supports the idea that an atomistic perspective of perception cannot explain rhythmic auditory stimulation and, consequently, the melodic music experience as a perceptual phenomenon. Katz says, that in a succession of metronome oscillations, different

rhythm patterns can be heard depending the speed of the beat. For this author, the dynamic organization of auditory figures is essential for the experience of rhythm.

This molar view of the act of perception fits with the existence of perceptual constancies. Perceptual constancy is an invariance of meaning within a given perceptual category. Even if one discrete characteristic of a target varies, our recognition of the target category does not vary. For example, viewpoint invariance (Goldstein 2010) is the ability to visually recognize a known object, despite it being presented from different angles. Another perceptual constancy is size, seen in the capacity to recognize a moving object although it is displayed in different sizes because of changes in distance. Color constancy is another basic constancy that brings simplicity to the multiple and variable stimulus world in which we live. Color constancy brings the possibility to group different palettes of tonality (turquoise, indigo, cobalt, sapphire, azure), as the same color, blue. From a gestalt view, the whole remains separate from its specific parts.

In short, the core of Gestalt theory may be summarized by the classic slogan, “the whole is greater than the sum of its parts” (Boring 1929, pp. 588–589). This whole may be observed in everyday examples such as perception of auditory melodies, in which notes sound different in the context of the melody than if they are heard in isolation. In taste perception, the combination of several flavors results in a totally different whole than the isolated ingredients. In this regard, another example widely explored in animal learning is the taste flavor paradigm. It is a well-known phenomenon in which a two-flavor compound tastes qualitatively different from each component tasted separately (Rescorla and Cunningham 1978).

Besides the aforementioned ideas, the Gestalt perspective introduced inference into the perception process. Perception is the act of grouping the myriad stimuli in the environment into dynamic wholes (Ellis 1938). For the Gestalt psychologist, perceivers are active organizers of stimuli. Gestalt psychology defended the experimental study of perception as a flexible status to fit and adapt to

the environment, working between exteroception, interoception, and cognition in an organizational way.

The basic topics of gestalt theory (Boring 1929) include the study of principles of relativity and transposition, related with generalization and discrimination processes in different perceptual variables. In this case, differentiating indigo from other blue tonalities is a discrimination exercise. Conversely, deciding that turquoise is also blue is an example of generalization. Additionally, in early Gestalt works, other principles to explore were the underpinnings of object constancy, field dynamics, and laws of form.

The rest of the entry is divided into three sections. The first is a historical overview of the principal authors from Gestalt psychology. The second is an exposition and synthesis of the Gestalt laws. Although the majority of the examples in the literature are on visual reorganization, gestalt laws may be observed in all perceptual modalities. Thus, perception is to see, hear, touch, smell, or taste from a scheme of meaningful organization. An assortment of examples will illustrate these principles. In the third and final section, the relationship between gestalt theory and general cognition will be discussed.

## Origins of Gestalt Theory

Gestalt psychology was developed primarily by Max Wertheimer, Wolfgang Köhler, and Kurt Koffka, in the first decades of the twentieth century. These authors were German psychologists who began their careers together at the Berlin Psychological Institute.

Max Wertheimer (1880–1943) published what many consider to be the first work of Gestalt psychology in his 1912 paper on the *phi* phenomenon (Wertheimer 1912). In this phenomenon, participants perceive illusory motion when they are presented with a sequence of spatially displaced images (Wagemans et al. 2012). In the original procedure, participants were exposed briefly to a line, followed by a short delay, and then by a second line, parallel to the first, and spatially separated. When the delay was below a

certain threshold (about 30 ms), participants perceived only one, stationary line; when the delay was above a certain threshold (about 200 ms), participants correctly perceived two lines, one appearing after the other; however, when the delay was at a certain middle value (about 60 ms), participants perceived a single line in motion. This final illusory motion effect is the same one that underlies our perception of motion in films, which consist of a series of static images. Wertheimer concluded that motion perception emerged as a perceptual whole, or *gestalt*, that was qualitatively different from any of its separate elements. This finding thus served as a starting point for the development of Gestalt theory (Wagemans et al. 2012).

Wolfgang Köhler's most essential findings came from his experiments on chimpanzee intelligence, published in *The Mentality of Apes* (Köhler 1925). In these experiments, Köhler (1887–1967) set out to test the extent to which chimpanzees could manipulate the environment or use tools to obtain food that was out of reach. For instance, in one experiment, a basket of fruit was hung in the air, with some boxes placed on the ground off to the side. The only way for the chimps to reach the fruit was to stack the boxes on top of each other underneath the fruit basket and climb them. Some of the chimpanzees tested (although not all) in fact did this. In another experiment, the only tools available to the chimpanzees were a pair of short sticks that they needed to insert into each other to create a longer stick able to reach the fruit basket and knock it over. One chimpanzee in fact did this. In another experiment, the only solution was to use a short stick to reach a longer stick and then use the longer stick to knock over the fruit basket. Several of the chimpanzees were able to solve the task.

Importantly, in all these experiments, the chimpanzees received no explicit training with the tools involved. Rather, it appeared that they came upon the solution through what Köhler called insight: a mental process in which the elements in the environment came to be perceived in relation to each other as a unique stimulus whole that made the solution obvious, as in an “aha” effect. Köhler described that, when faced with

each problem, the chimpanzees initially tried to reach the food directly with their hands, but eventually gave up that futile approach and appeared to sit in thought for a while, examining the surroundings. The chimpanzees' attention eventually focused upon the available tools and, a few moments later, the chimps proceeded to use the tools more or less correctly for the purpose of obtaining the food. Köhler argued the core of this insight process was the perception of the complete environment and all of its parts in relation to each other, and a reorganization of the stimulus elements in the chimpanzee's mind to achieve a new perception that was qualitatively different from the sum of its separate parts. Köhler viewed this type of learning as fundamentally different from the mechanistic S-R learning proposed by another prominent psychologist of the time, Edward Thorndike (Ruiz and Sánchez 2014), whose theory might predict that the chimpanzees would arrive at the solutions only gradually and through trial and error. Köhler observed quite the opposite: that the solution appeared rather swiftly after a careful reflection of the situation.

Kurt Koffka (1886–1941) contributed to the development of Gestalt theory with the publication of works such as *Principles of Gestalt Psychology* (1969). As Goodwin (1999) recalled, Koffka did his PhD in Berlin exploring perceptual contrast of color and the study of rhythm in auditory stimuli (Goodwin 1999). Koffka also got involved in Wertheimer's apparent motion experiments, as did Köhler. His work built upon that of Wertheimer and Köhler and applied it to new areas such as child development. Like his colleagues, Koffka also sought to distinguish gestalt theory from the prevailing behaviorist theory of the time. He argued that while behaviorists, such as Thorndike, refused to study conscious mental phenomena, gestalt theory tackled these phenomena directly and successfully. Furthermore, Koffka spent the later part of his career as a professor in American universities such as Cornell, the University of Wisconsin, and Smith College, and as such was the main promoter of the Gestalt perspective in America.

## Gestalt Laws of Form

Besides explaining perception in terms of schemas of meaning, Gestalt psychology formulated the Laws of Gestalt. These laws summarized the general trends of how we organize our perceptual world. First studied by Wertheimer between 1923 and 1967 (Goodwin 1999), Gestalt laws assumed that elements are organized as part of a meaningful whole. This organizational principle underscores the ultimate purpose of the perceptual process, to find meaning in the chaotic world of stimuli that surrounds us. Each law exposed below organizes figures through a common purpose, soft lines, symmetrical order, space distribution, similar features, or same orientation. Gestalt organization also tends to the maximum simplicity that encourages the maximum effectiveness of perceptual effort. For instance, Fig. 3 shows a simple example of gestalt organization. A plain set of two points and a line are quickly organized as a schema of a human smiling face.

As Boring first claimed (1929), Gestalt principles form the basis for 114 laws of perception. However, the main rules that appear in basic perception manuals can be grouped as follows.

1. **Good Form or Pregnancy.** This law, also known as Common Destiny or Simplicity, was formulated by Koffka (1969). This law states that elements that share a common end, following the simplest principle, tend to be considered as being from the same figure. A common end could be a meaningful category or schema. This rule helps the perceiver to differentiate parts from different objects that visually overlap with each other (Katz 1945), as Fig. 4 shows. It also operates when there are several options of figures in the perceptual field. The constellations in astronomy are pure examples of gestalt pregnancy. Figure 5 shows the basic stimulus input that comprises the Ursa Major constellation and the schema that provides the image of a bear. Another interesting example in another sensory modality is the effect studied by Benussi (in Katz 1945). In this tactile effect, the stimulation provoked by three points of pressure in

**Gestalt, Fig. 3** Example of organization

**Gestalt, Fig. 4** Delimitation of geometric figures from Good Form law. Example of delimitation of edges following the geometric schemas of pentagon, circle

the skin, delimiting a triangle, is perceived as a circle sensation.

2. **Closure.** Human perception tries to complete or close figures (Katz 1945). People prefer closed to unclosed figures (Wertheimer 1923). This tendency to complete incomplete sensorial information takes place in an automatic way. All the information provided to help to finish a contour will be selected to outline a whole, as Kanizsa showed in his varied incomplete triangles and other invisible border images (1976). A proof can be seen by removing a part of any geometric shape, a triangle for example. In Fig. 6, one can observe the difficulty of ignoring the whole shape despite being incomplete. An example from the auditory domain is known as auditory closure strength, the ability to listen to the whole message in a radiophone speech with interference (Katz 1945). An example of the same phenomenon in a visual-reading domain can be seen in Fig. 7.
3. **Continuity or Good Continuation.** Human perception tends to complete lines but also softly, and tends toward the circle shape (Wertheimer 1923). For example, motor integration involves a preference for indirect and

**Gestalt, Fig. 5** Draw Illustration of Ursa Major. Exemplification of Gestalt Pregnancy. A bear figure can be perceived from a few spots in the sky. (From: Pixabay)

**Gestalt, Fig. 6** Examples of geometric closure. Triangle and circle are visible for the closure gestalt law

# gestalt

**Gestalt, Fig. 7** Example of Closure in reading

circular movements in the perception of human motor translation. In Fig. 8, one can see a clear example of continuity in which the viewer tends to perceive two softly curved lines, rather than pointy shapes. In another example, from ethology, there is a preference for soft and circular shapes in mammalian offspring. Lorenz (1943) showed that similarities exist in some physical characteristics of young animals, such as round faces. Maps also can be a good model of continuity; we are able to distinguish geographic delimitations from many overlapping lines.

4. **Symmetry.** Figures are usually perceived as symmetrical. Asymmetries tend to be neutralized (Katz 1945). This principle completes and emphasizes the aforementioned rules

**Gestalt, Fig. 8** Example of Good Continuation. Facing the task of determining the start and end of those two lines, Good Continuation predicts the limits of one from *a* to *d*, and the other from *b* to *c*, due to a preference for soft lines over sharp corners. The scheme of letter x in the Western alphabet may also be influencing (Adapted from Katz 1945)

and shows a perceptual preference for homogenous images and sensorial perceptions. Also, the objects that tend to be symmetrical, that is, those equally distributed around their axis, are easily perceived and selected.

5. **Proximity.** Stimuli near each other tend to form a unity (Wertheimer 1923). Good examples of this are from auditory perception of musical patterns. A piece played slowly, or “lento” in musical terms, can hardly be heard as the same piece when it is performed quickly, or “presto.” Another auditory phenomenon is that of auditory segregation, which is similar to the proximity effect (Bregman and Campbell 1971). In the original experiments, these authors presented an alternating sound sequence of low (between 350 and 550 Hz) and high tones (between

2500 and 1600 Hz). When the sequence was played slowly (interstimulus-interval of 400 ms), a pattern of successive low and high stimuli clearly appeared. When the same sequence was presented faster (interstimulus-interval of 100 ms), the perception was divided into two auditory paths: a high one and a low one. This segregation effect, due to temporal proximity between similar sounds, can be experienced in the classical music opus S. 141 study of Litz, commonly known as “Campanella.” In Fig. 9, one can also see a visual example. The elements in each set of points are the same, but they differ in its spatial distribution, creating a very different visual result.

6. **Similarity.** Stimuli that share features tend to form a unity. Lightness, color, texture, size, shape, (Goldstein 2010) are possible characteristics to be grouped, as can be seen in Fig. 10. In a complex visual pattern, as a Monet painting, the figures can emerge from the similarity of color, size, and texture of the brush strokes, as can be seen in his studies of “Water Lilies.” The similarity principle is evident in the painting style of lots of impressionistic artists. Moreover, a painting technique called pointillism uses similarity and gestalt principles, using the different color points to conform the scenes, as Van Gogh and Seurat did.
7. **Good direction or Common fate.** This principle takes into account the movement or tendency to group elements in the same direction (Wertheimer 1923). Orientation and synchronicity in the static figures is relevant to define figures. In Escher’s paintings, common

fate is a clue to discern the different illusions hidden in each drawing, like in his series “Sky and Water.”

8. **Strong form.** A strong or intense stimulus tends to be differentiated from other stimuli. If a strong stimulus competes with a weak stimulus, the strong stimulus tends to attract more attention. This is the case of the reorganization process called reification, the ability to see more information than is actually provided by the physical stimuli. The subject gives additional attributes in order to organize intense meanings. This reification process is governed by powerful meaning. Something similar happens in the pareidolia phenomenon. This cognitive process occurs when perceivers are able to distinguish concrete forms in a simple environment, like an artificial apparatus or a natural phenomenon. An example of this is the common example of seeing animals, faces, and other significant figures in the clouds. Something relevant in all these processes is considering that human faces are strong stimuli for human perception. This principle is reflected in the perception of a facial expression in Fig. 3. Similarly, in Fig. 2, one image is usually more difficult to see than the other. Sometimes, familiarity gives the stronger value to one option over another. This principle supports the next law to be considered in terms of differentiating strong figures from weak ones, which sometimes can be considered as background.
9. **Figure and Ground.** Human perception tends to fixate on one main point over the background. The figure has a defined outline that stands out from the ground. This principle

**Gestalt, Fig. 9** Example of proximity. The same stimuli form different configurations (horizontal or vertical, respectively) depending on a proximal variable

**Gestalt, Fig. 10** Similarity example. Columns of points tends to be grouped by shade identity

**Gestalt, Fig. 11** On the *left* are the Rubin faces, a classic example of Figure and Ground. On the *right*, a combination of shades between Figure and Ground (Adapted from Rubin 1921)

explains why perceivers need a certain contrast to distinguish figures (Oviedo 2004). The first description of this principle was by Rubin (1921) and was illustrated by the classic faces and cup image, as can be observed in Fig. 11. Another example of the influence of ground in the perception of a figure is the visual differences depending on the color of possible backgrounds (see Fig. 11). Also, in Fig. 2, the hidden figure can be conceptualized as ground, since it is not possible to perceive both women at the same time. Koffka (1969) exposed an analysis of characteristics in which figure and ground are related, including factors such balance in color, limits of the figure contour, orientation, relative size, and feature complexity. In another perceptual paradigm, Signal Detection Theory (Green and Swets 1966) has widely developed the task of finding a figure (a Signal, in the terms of the theory) from the

Ground (Noise, in the parlance of the theory). The particularity of this theory is the systematic study of different ambiguity conditions of figure and ground. Signal Detection methodology explores the measures of probability to perceive and decide between response or no response to the signals and possible false alarms that can be confounded with the ground.

10. **Stability.** When organizations are established, they are also difficult to eliminate and tend to persist. Gestalt perception tries to conform stable objects. For example, in visual illusions like the Necker cube (check Fig. 1) and the younger and older woman (see Fig. 2), the option not seen at first sight, is usually more difficult to see.

From all these laws, Closure, Good Continuation, Proximity, Similarity, and Figure and Ground are the most general and commonly observed. In lots of everyday examples, various laws work together. Several applied fields have explored the extent of these principles, with logos and advertisements serving as good examples of this. Also, analysis of visual art has made a lot of effort to apply gestalt principles to art perception.

## Gestalt Perception Theory and Learning

Gestalt principles have served as a platform for studying animal learning and cognition in a variety of contemporary research. One manner in which this has been done is through the study of perceptual laws outlined above, in animals. Studies of the perceptual constancies have been performed in species as diverse as parrots (Pepperberg and Nakayama 2016), ants (Sakiyama and Gunji 2016), mice (Kanizsa et al. 1993), and chimpanzees (Hopkins and Washburn 2002).

For instance, Pepperberg and Nakayama (2016) tested, in a parrot, the phenomena of amodal and modal completion. Amodal completion is the recognition of an object that is partially covered, such as the square in Fig. 12a. Modal

completion is the recognition of an object that lacks some of its boundaries, such as the square in Fig. 12b. Notice that the phenomena rely on the gestalt principles of good form and closure. Pepperberg and Nakayama tested whether a parrot could identify incomplete two-dimensional (2D) shapes similar to the ones in Fig. 6 after having been trained to verbally identify the corresponding three-dimensional (3D) shapes. They found that the parrot was indeed able to identify the incomplete 2D shapes, whether they required amodal or modal completion. Importantly, the parrot had previously been trained only with 3D shapes, and had never been tested with their 2D counterparts, let alone 2D shapes requiring completion. While the authors acknowledged that the exact mechanism underlying the results is not clear, the finding at least provides evidence that parrots might engage in a “gestalt”-style processing of the world, possibly reflecting higherorder cognitive abilities.

Another aspect of modern learning and cognition that draws a parallel from Gestalt psychology is the concept of configural, as opposed to elemental, processing (Wasserman 1997). Elemental processing refers to a bottom-up processing of the

individual parts of a stimulus set, whereas configural processing refers to processing the complete stimulus set as a whole, akin to a gestalt. For instance, suppose an animal is presented with a light and tone simultaneously, followed by food. Elemental processing would be said to take place if the animal forms two distinct associations, one between the light and food, and another between the tone and food. Configural processing would be said to take place if the animal forms a single association between the light-tone configuration and food. Some modern learning theories use the concept of configural learning (e.g., Pearce 1987), and a number of findings suggest that configural associations play a role in animal learning (for a review, see Pearce and Bouton 2001). Other research suggests animals may engage in both types of processing in varying degrees (Honey et al. 2014).

A related concept in modern learning and cognition drawing inspiration from Gestalt psychology is that of global, as opposed to local, processing (Navon 1977). For instance, imagine one is asked to discriminate between hierarchical stimuli, such as those shown in Fig. 13, involving large letters made up of small letters. Local processing would be defined as focusing attention on the small letters, while global processing would involve focusing attention on the large letters, as in “seeing the forest before the trees.” Hopkins and Washburn (2002) trained chimpanzees and rhesus monkeys on discriminations between hierarchical stimuli similar to those shown in Fig. 13. The authors found that while rhesus monkeys performed better when the discrimination was between the small letters (local processing), the chimpanzees performed better when the discrimination was between the large letters (global processing). The global processing exhibited by the chimpanzees may be interpreted as a gestalt

**Gestalt, Fig. 12** On the *left*, a square requiring amodal completion; on the *right*, a square requiring modal completion

**Gestalt, Fig. 13** Local and global processing

processing of the whole stimulus. More generally, there appears to be a relationship between cognitive complexity and global processing (Neiworth et al. 2006). In a study that compared adult humans with children and adult tamarin monkeys, adult humans showed the strongest tendency towards global processing, while children and adults tamarin monkeys showed similar, lower levels (Neiworth et al. 2006).

As the preceding findings show, Gestalt-inspired principles serve as a useful basis for studying animal learning and cognition, as well as for performing cross-species comparisons. The general presumption is that the level of gestalt processing reflects the level of cognitive complexity, although the specific underpinnings of such processing remain unclear.

## Conclusion

Gestalt psychology defined perception as an active way to organize the stimuli that surround us. From first decades of the twentieth century, the primary Gestalt authors (Wertheimer, Koffka, and Köhler) experimentally studied the principles and laws which describe the general trends of how we group sensorial information. The Gestalt perspective changed the general conceptualization of the study of cognition, emphasizing that molar processing in perception could influence other basic psychological processes.

## Gestation Stall

Emily Patterson-Kane  
Animal Welfare Division, American Veterinary  
Medical Association (AVMA),  
Schaumburg, IL, USA

## Synonyms

Individual sow accommodation; Sow stall

## Definition

A metal enclosure used to house an individual breeding sow during pregnancy.

## Introduction

Pregnant sows may, in some agricultural systems, be kept in small individual pens. Sows are typically kept in these stalls until several days before their expected parturition date when they are moved to farrowing crates. Gestation stalls are made from metal pipes or bars and are often approximately 6.5 feet long by 2.5 feet wide. Food and water is provided at the front of the stall, and, at the rear, a slatted floor allows manure to be collected in a pit underneath the building. The stall is long enough for the sow to take a few steps forwards or backwards, but the width of the stall does not allow the sow to turn around.

Gestation crates are an example of a housing system of extreme confinement, epitomizing the advantages and disadvantages of this approach to farming animals for meat. Crates contribute to highly efficient systems that produce abundant supplies of meat at a relatively low cost. Crated animals can be easily controlled, inspected, fed, and protected from outside hazards such as extreme temperatures, parasites, or predation, and the potential for inter-sow competition and aggression is greatly reduced. However, this efficiency is at the cost of the animals being able to engage in normal social interaction, perform natural foraging, or nesting behavior, move more than a few steps at a time or turn around. As such, it challenges the idea of how animals should live, and whether it is reasonable to keep them in such small and barren environments.

## Alternative and Comparisons

Other systems for housing gestating sows include larger individual pens, group pens, hoop barns, and free range (outdoor pasture).

Stall housing is associated with abnormal repetitive behaviors (“stereotypies”) thought to indicate poor welfare, and animals housed in this manner are prone to certain kinds of injury such as pressure sores. However, most other objective measures of health and productivity do not differ significantly for animals housed in stalls versus

other housing systems (AVMA 2015). When sows are group housed, management practices need to be employed to control aggression and ensure that all of the sows have access to food and other resources.

## History

After World War II, Europe and the United States had moved towards raising pigs indoors to control parasites and improve efficiency. Gestation crates were widely adopted by new farms beginning in the 1970s. The housing of sows in confined, individual crates from farrowing to weaning of the piglets had already become common by this time, and extending stall housing throughout pregnancy provided farmers with a number of advantages: the sows occupied less space than in group pens and waste was more easily managed. For these reasons, crate housing often reduces the costs of production and increases productivity (McGlone 2013). Individual housing can also be justified as a method for reducing competition between animals and ensuring that all animals receive sufficient feed, protection, and other individual attention.

As stall and crates were emerging as a dominant system for commercial pig farming, confinement systems were also being challenged as inhumane “factory farming” – for example, by the book “Animal Machines” (Harrison 1964). The degree of confinement imposed by gestation crates has been further exacerbated as their dimensions have generally not been increased sufficiently to accommodate the increasing size of commercially farmed pigs (McGlone et al. 2004).

## Public Attitudes

Sow crates are a frequent subject of the broader debate about how to weigh the different aspects of animal welfare, with increasing emphasis being placed on indications of mental health and opportunities to perform natural behaviors. On this basis, in North America, a majority of the public

support banning the use of gestation crates (Tonsor et al. 2009), and, when surveyed, individuals who were taught more about how these systems are used tended to exhibit stronger disapproval (Ryan et al. 2015).

## Conclusion

Gestation crates were initially welcomed as a modern system that benefited sows’ physical health, and the safety, and cost of pork. Over time, the degree of confinement that crates impose on animals has been demonstrated to negatively impact their mental health, and the use of crates is now unpopular with consumers in developed nations in America, Europe, and Australasia.

## Ghost Control

Lydia M. Hopper

Lester E. Fisher Center for the Study and Conservation of Apes, Lincoln Park Zoo, Chicago, IL, USA

### Definition

An experimental technique used to differentiate social learning mechanisms.

### Introduction

The “ghost control” is an experimental technique used to tease apart social learning mechanisms (Hopper 2010). When learning from watching the actions of others, a naïve observer may faithfully copy the bodily actions of the expert (i.e., imitate them) or they may learn about the environmental changes caused by the actor and reach the same goal through their own means (i.e., emulate them) (Wood 1989). In a ghost control, the animate model is removed from the demonstration, making it look as if the task were acted upon by “a ghost.” The researcher can then measure subjects’ abilities to learn from, and replicate, methods shown in ghost control displays in comparison to observing live (often conspecific) models. Thus, the ghost control is one method that can be employed to help tease apart social learning mechanisms, namely to distinguish imitation from emulation.

### Theory

The theory underlying ghost controls is most clearly exemplified by an idea put forth by Michael

Tomasello in his book *The Cultural Origins of Human Cognition*. Tomasello asked the reader to consider the following hypothetical scenario involving wild chimpanzees: “if a mother rolls a log and eats the insects underneath, her child will very likely follow suit. This is simply because the child learned from the mother’s act that there are insects under the log – a fact she did not know and very likely would not have discovered on her own. But she did not learn from her mother how to roll a log or to eat insects; these are things she already knew how to do or could learn how to do on her own. (Thus, the youngster would have learned the same thing if the wind, rather than the mother, had caused the log to roll over and expose the ants.) This has been called *emulation learning* because it is learning that focuses on the environmental events involved – the changes of state in the environment that the other produced – not on a conspecific’s behavior or behavioral strategy” (Tomasello 1999, p. 29). Following this idea, a ghost control condition would equate to the wind rolling the log, while the experimental condition would provide a live model, akin to the mother chimpanzee in Tomasello’s example.

### Methodology

To create ghost control displays, researchers have employed a range of techniques – both digital and mechanical – to provide a demonstration without a social model. Typically, the social model is omitted altogether and a hidden mechanism is used to move the apparatus, for example via near-invisible fishing-line (e.g., Hopper et al. 2015) or with magnets (e.g., Loukola et al. 2017). In contrast, some researchers have used video manipulation either to digitally remove the actor from video footage shown to observers (e.g., Huang and Charman 2005) or to crop the frame to eliminate the actor from view (e.g., Flynn and Whiten 2013). Lastly, in tests of social learning using touchscreen interfaces, stimuli on the screen have been programmed to automatically show the required pattern of responses without the need for a social model to demonstrate them (e.g., Subiaul et al. 2004).

## Species Tested

The ghost control technique has been used extensively with human children (e.g., Thompson and Russell 2004) and nonhuman primates (e.g., Hopper et al. 2015), and also with dogs (e.g., Miller et al. 2009), birds (e.g., Fawcett et al. 2002), reptiles (e.g., Kis et al. 2015), and even insects (e.g., Loukola et al. 2017). Hopper (2010) provides a review.

## Criticisms of the Ghost Control

It has been argued that the ghost control has limitations as a test for emulation as it lacks validity (Howard et al. 2017). For example, the ghost control display might not be equally engaging to the viewer as a demonstration provided by an animate model. In turn, reduced attention to ghost displays, in comparison to animate models, might translate into reduced learning. Additionally, naïve observers may be less likely to learn from ghost control displays, than from socially provided demonstrations, because the movements shown in ghost controls may appear implausible and as if they defy the laws of physics. Therefore, to differentiate imitative from emulative learning, researchers have employed comparable but different controls, such as the end-state method (Hopper 2010), or by showing observers animate models with agency *versus* inanimate models that lack agency (Howard et al. 2017).

## Gisela Kaplan

Lesley J. Rogers  
School of Science and Technology, University of  
New England, Armidale, NSW 2351, Australia

### Prehistory

Gisela Kaplan grew up in West Berlin and migrated to Australia in 1968. She is a field biologist and emeritus professor of animal behaviour at the University of New England (UNE), Armidale, New South Wales, and also serves as honorary professor at the Queensland Brain Institute. Her fields of research have been largely in primate and avian cognition and communication with an increasing focus on Australian avian species.

Her career in animal behaviour started rather late in life and was preceded by an entirely separate career in literature and social science (sociology and psychology, both as major study areas). As an overseas applicant, she completed a higher school certificate in Melbourne and won a coveted Commonwealth Scholarship for Excellence (top 4% of results statewide), despite

substantial hurdles of having had to learn English at the same time as taking the subjects. Kaplan came from a humanistic schooling background (a selective lyceum) in which Latin, Old Hebrew and Greek were taught but, at that time, not necessarily English. She chose to study at Monash University, and there, she completed a BA (Hons first Class) and a postgraduate diploma in education qualifying her as a secondary school teacher. At the end of that qualifying year, she was awarded a Commonwealth Postgraduate Scholarship for Excellence and enrolled in a Masters of Arts (awarded in 1978) and then in a PhD. Throughout her PhD, she taught night classes and took on projects such as translating the work by German anthropologists into English and translating Sir Monash's letters to his father for a book. On being awarded her first PhD in 1984 at Monash University, she advanced very quickly through the ranks at various universities and was appointed foundation professor of social sciences in 1990, serving as head of the newly formed school at the Queensland University of Technology. In that time, between 1989 and 1996, she published six books and many papers, working on social movements, social injustice and racism. This led also to the prestigious Gustavus Myers Human Rights Award in 2002 for the joint project of *Challenging Racism and Sexism* (1994, edited by E. Tobach and B. Rosoff) by offering explanations alternative to genetic determinism. Later, her joint book with Lesley Rogers brought together the social and the scientific critique of social and scientific biases (Kaplan and Rogers 2004).

### Changing Career

These activities and scholarly engagements seemed a long way off animal behaviour, and indeed, they were, had it not been for some exceptional opportunities that became career changing. In extensive field research of orangutans (*Pongo pygmaeus*), undertaken in team work with Prof Lesley Rogers, Kaplan began investigating innovative and cognitive behaviour, hand preferences and inter-species communication, reflected in a series of joint papers and in three books devoted

entirely to orangutans, the first being published in 1994.

Kaplan and Rogers then established a colony of common marmosets at the University of New England to enable close-up primate research on perception, lateralisation, communication and a range of welfare issues. The colony attracted many postgraduate students and produced a volume of papers and PhD theses over more than a decade. The combination of field work with orangutans in Borneo and laboratory/purely behavioural work with common marmosets enabled a broad view of great apes versus New World monkeys and raised issues of social organisation and evolutionary and cognitive questions both within primatology and in animal behaviour in general. For a considerable time, UNE became the only facility in Australia in which primate behaviour could be studied to PhD level on tertiary campus grounds well equipped and especially designed for behavioural studies. Kaplan then served on the international scientific committee of the International Primatological Society (IPS) and is a life member of that organisation.

By 2004, it became clear that the primate-centric approach to cognition had to be examined more closely. Kaplan, together with Rogers, put together a substantial edited volume asking precisely whether, indeed, primates are cognitively superior to other species. It was the first major publication on the topic (Rogers and Kaplan 2004).

Kaplan's interest in animal behaviour was more and more drawn to birds. While studying orangutans was within Kaplan's qualifications (incl. Experimental/comparative psychology), the study of bird behaviour was not. Kaplan thus enrolled in a second PhD at the Veterinary School at Queensland University, spending years acquiring a classic ethological training as well as a sound veterinary science background. Her thesis analyzed general development, vocal development and communication in Australian magpies, using data collected over thousands of hours of field-work. This detailed study, conducted beside near full-time academic work and the only study of a single Australian avian species, not only gained her a second PhD (2005) but also the coveted

Dean's Commendation of Veterinary Science for Outstanding Original Research (2007).

Kaplan started out again as a junior research scientist, moving quickly through the career stages to senior research fellow, and was appointed professor of animal behaviour in 2007 at the University of New England, by which time she already had accumulated a substantial number of publications in animal behaviour including eight books jointly authored with Lesley Rogers.

Professor Gisela Kaplan has become a very eminent voice in animal behaviour and particularly bird behaviour and cognition, reflected in substantial research papers and a substantial number of books, many of them noted internationally and bestsellers, as well as a string of awards, among them the prestigious Whitley Award for Behavioural Zoology for her book *Bird Minds* (2015). This and her latest book, *Bird Bonds* (2019a), have had strong positive international attention (e.g. reviews in *Animal Behaviour* and in one of the oldest and most prestigious American ornithological journals *The Auk*). In 2014, she was elected an honorary corresponding member of the American Ornithological Society (AOS), a society that maintains an honours list of the 100 most eminent extant avian scholars worldwide, outside the USA and Canada. In 2011, the University of New England awarded Prof Kaplan an honorary doctor of science, and in 2016, she was appointed emeritus professor in animal behaviour.

## Research Emphases

Kaplan has found a very rich field of study in Australian native birds, being inspired by the taxonomical findings between 2002 and 2011 which confirmed that modern songbirds first evolved in Australia (then East Gondwana). Indeed, some 22 lineages are said to have survived the mass extinction events of 56 million years ago, including the stem lineages for cockatoos and possibly other psittacines.

One of her major contributions to avian and cognitive studies lies partly in the reassessment

of behavioural and cognitive traits in birds from an evolutionary perspective and redressing almost single-handedly the previously held assumptions about modern birds' origins in the northern hemisphere. Australian birds thus offered her opportunities to study the original lineages from which later emigrants to other continents may have diverged and speciated (Kaplan 2015, 2019a).

Her model species became the Australian magpie, a member of the broader Corvida and widespread across Australia. Her research and ideas have focussed on this project, conducting groundbreaking research into vocal learning, communication (Rogers and Kaplan 2000) and cognition (Kaplan 2019b). The project, over a 25-year period, involved in-depth examination of their vocal and cognitive abilities, studying the song control system (Deng et al. 2001), their physiological preconditions for song performance (Suthers et al. 2010), how juveniles learn (Kaplan 2017b, 2018a) and manifestations of hemispheric specialisations in vision (Koboroff et al. 2008) and audition (Kaplan 2017a). Magpies have a number of unusual attributes such as a substantial song repertoire not typically associated with territorial songbirds, and males and females sing alike and all year round (Kaplan 2008a). Kaplan documented that both males and females are capable of extensive mimicry of other species, including human voices (Kaplan 2000, 2004). Furthermore, Kaplan uncovered the multitude of signal characteristics of magpies, including special referential signals (Kaplan 2008b; Kaplan et al. 2009; Kaplan and Rogers 2013). Kaplan's project showed that successful maintenance of territory is built on clever strategies (Koboroff et al. 2013).

Kaplan was the first to discover pointing behaviour in an avian species (Kaplan 2011) and the first to study complex cognitive and affective behaviour in Australian land birds as a whole (Kaplan 2015), inviting searching questions about the cognitive and social requirements for which biological adaptations had to be made (Kaplan 2019a, 2020). She also conducts research with other species, such as tawny frogmouths (Kaplan 2018b), zebra finches (Rogers et al.

2018), a number of psittacine species Kaplan (2020b) and even the domestic chicken (De Tommaso et al. 2019). Kaplan is a member of the International Ornithology Union (IOU) and has served on its executive.

Over both careers, Kaplan has authored more than 250 research articles and published 23 books and is a constant presence in the media. She has been called one of the most prominent science communicators in Australia. Indeed, she has brought knowledge of the behaviour and life histories of Australian birds close to the general public, be this via books and radio programmes, podcasts, speaking engagements or personal e-mails to listeners or readers. In her spare time, Kaplan rehabilitates native birds under license and has done so for the past 25 years.

## Synonyms

### Stop-Signal Task

## Definition and Specificity

The Go/No-Go (GNG) procedure is an experimental paradigm designed to probe, primarily, behavioral response inhibition. The task involves a continuously presented series of stimuli composed of frequent Go cues and less frequent No-Go cues. Subjects respond to stimuli either by executing (to Go cues) or by withholding (to No-Go cues) a behavior, such as pressing a designated key. It is essential to the GNG task that

Go cues are presented more frequently than No-Go cues so that response to the former is automatic and response to the latter is effortful. In human studies, the two types of stimuli are typically presented in the auditory or visual modality.

Tasks similar to the GNG task include the Two-Choice Task and the Stop-Signal Task (SST). In the Two-Choice Task, subjects are typically required to respond to a stimulus using one of two possible choice responses. The spread of response time (RT) distributions in the GNG task was reported to be larger than that in the two-choice task (Gomez et al. 2007), which may be of significance when RT is applied to compare individuals scoring low vs. high on some trait (e.g., Liu et al. 2015). The Stop-Signal Task (SST) is considered functionally equivalent to the GNG task in capturing individual differences in inhibiting actions and impulsive behavior (Verbruggen et al. 2019). Despite similarities, there is also an important difference; the former is used to test the ability or failure to withhold a response before its execution (action restraint), whereas the latter assesses the ability or failure to inhibit a motor response during its execution (action cancellation) (Eagle et al. 2008). In the fields of neuroscience and psychology, the SST is a well-established tool to study response inhibition across human and nonhuman populations. The paradigm combines two concurrent tasks; participants typically perform a two-choice Go task (pressing different keys depending on the provided stimuli), but on a minority of the trials, a predetermined stop signal appears requiring subjects to suppress the prepared or initiated Go response. It is important to note that direct comparison of the GNG and SST indicate distinct underlying neural mechanisms and dynamics, implying that interchangeable use of the two superficially similar inhibition tasks is unjustifiable (Raud et al. 2020).

## Design and Measured Variables

Being a relatively simple task, when designing a GNG procedure, three parameters need to be

determined; the proportion of Go relative to No-Go trials, the total number of trials, and the RT window.

There is great variability across studies with respect to both the proportion of the two types of stimuli and the total number of trials.

An underlying assumption of GNG tests is that the Go response is more automatic; as such, it can be withheld only via recruitment of inhibitory functions and processes. For the Go response to be more prepotent, the Go stimulus must be presented more frequently than the No-Go stimulus. In case of too frequent No-Go stimuli, participants might tend to wait for a No-Go trial to occur, resulting in differences in performance (e.g., slower RT to Go trials as a result of expecting those to be No-Go trials) caused by diverse strategies to anticipate No-Go trials. Although this basic principle is widely accepted, a great number of studies use equiprobable Go/No-Go trials. To test whether applying such equiprobable tasks elicit prepotent motor activity and probe inhibitory control, EEG data were recorded during four GNG tasks, varying in No-Go rate and trial duration (Wessel 2018). Findings revealed that only fast-paced GNG tasks with rare No-Go trials reliably evoked relevant brain activity. Therefore, it is suggested that in proper GNG studies a maximum of 25–40% No-Go trials are used, to reliably evoke prepotent motor activity, otherwise the inhibitory requirements of the tasks are greatly reduced, which has major implications for the usage of the paradigm in experiments. In some functional magnetic resonance imaging studies, the proportion of No-Go trials can be 10% or less, accompanied by a very high (>1000) number of total trials (e.g., Kaufman et al. 2003). Although reliability increases with the total number of trials, adding more trials than the minimum necessary is not always feasible, considering that factors other than inhibition, such as decreasing attention or motivation and/or increasing frustration, may have a confounding effect. The selected time window may also move in a wide range depending both on the given GNG procedure and the research question.

Despite its apparent simplicity, these three features of the GNG paradigm vary across studies in

ways that can affect the validity of the obtained results in comparative studies.

The basic dependent variables measured in a GNG procedure are two error types and the RTs for Go responses (and sometimes for erroneous hits to No-Go stimuli). The subject commits an omission error not executing a Go response on Go trials and a commission error making a Go response on No-Go trials. The analysis is typically based on calculating the commission error percent (the proportion of commission errors relative to the total number of No-Go stimuli), and sometimes also on the omission error percent (the proportion of omission errors relative to the total number of Go stimuli). In the most typical application of the GNG procedure, the primary function of interest, response inhibition (withholding a prepotent behavioral response), is indexed by the commission error rate, with fewer errors implying better inhibition. The secondary function of interest, attention, is indexed by the omission error rate, with fewer errors implying better attention.

RT is calculated as the average latency of correct Go responses (the elapsed time between stimulus onset and execution of a correct Go response). RTs for Go responses are informative about how the sequence of perception, decision-making, and action is organized. In a GNG task, unlike the latency of Go responses, the latency of response-inhibition cannot be directly observed. Conversely, the SST allows the estimation of the covert latency of the No-Go reaction, as the stop signal can be presented after a variable delay following the onset of the test stimulus.

## To Go or Not to Go?

That is the simple question subjects face many times in a row in the GNG procedure. However, what seems to be simple, can be pretty difficult, depending on the participant's temperament, personality, executive functioning, and attentional and motivational state.

The GNG is one of the most commonly used paradigms to assess response inhibition that is a crucial component of adaptive and goal-directed

behavior (Votruba and Langenecker 2013). It is essential for navigating everyday life without conflict and deficiencies in this ability can contribute to numerous neurological and psychiatric disorders. As described, in an experimental set up, response inhibition refers to the suppression of prepared or initiated actions and successful response inhibition results in the absence of an observable response. Research using the GNG task has revealed links between inhibitory control capacities and a wide range of behavioral and impulse control problems in everyday life (e.g., attention-deficit/hyperactivity disorder – ADHD; Barkley 1997) and revealed unique information about the underlying neurocognitive control mechanisms of impulse control. In GNG tasks, compared to typically developing peers, youth with ADHD exhibit more errors and slower RTs and their omission errors are primarily associated with inattention, whereas commission errors can be primarily associated with hyperactivity/impulsivity (Bezdjian et al. 2009).

Active choice by GNG paradigms has been also used to measure the effects of cognitive biases on emotional states and disorders (e.g., depression) in humans. Cognitive bias is a systematic pattern of responses; it occurs when an affective state or temperamental trait affects cognitive processes. This concept is based on findings that people in negative emotional states will show increased attention to negative stimuli and are more likely to make pessimistic interpretations of ambiguous situations (e.g., intermediate between Go and No-Go stimuli). Individual differences in cognitive biases in humans are related to dimensions of personality, attention, memory, and impulsivity (e.g., Marshall et al. 1992). Considering the findings on the links between response inhibition and ADHD symptoms, it should be noted that the results of GNG tasks employed to assess cognitive bias certainly reflect variations in characteristics beyond cognitive biases, such as in individual differences in attention and behavioral disinhibition.

In humans, neuroimaging techniques have also been used to find differences in brain response to Go and No-Go stimuli and thereby reveal the neural substrates of response inhibition.

The GNG procedure is relevant to assessing the association between task performance and important sociocognitive traits not only in humans. It is ideal for comparative research, as it is appropriate for assessment of human and animal subjects without considerable alterations to experimental or task design (Eagle et al. 2008).

## Application in Nonhuman Studies

Although human participants receive little to no training before GNG measurements, they do receive instructions on how to complete the task, such as to respond as quickly as they can. In contrast, animals need extensive pretraining for GNG measurements, which may have an impact on their performance. Choice tasks have been argued to be preferable to GNG tasks because they allow a general lack of motivation to respond to be distinguished from a pessimistic interpretation of an ambiguous stimulus, however, GNG tasks are usually faster to train. Animals are rewarded with food for every correct Go and No-Go response during the training sessions (Tremblay and Schultz 2000). Even during the test sessions, continuous reward might be needed for the correct choices, which can interfere with some test designs, for example, when an ambiguous stimulus is presented.

Following a classical training procedure, scent-detection variants of the GNG task involve training detection dogs to respond to the presence of a new target scent and not respond to control samples (Concha et al. 2019). In line with other animal studies, dogs are trained to sniff individual carousel arms without assistance from their handler, applying operant conditioning methods, using only positive reinforcement (food/ball reward) and negative punishment (no reward in case of false indications). Of note, in this version of the paradigm, RTs cannot be evaluated as the odor stimuli are presented simultaneously, using a multichoice carousel, which makes it impossible to apply a preset time window.

In contrast, introducing a slightly different training procedure, a more standard GNG

procedure has been used with companion dogs (Bunford et al. 2019a). Stimuli were presented by a touchscreen device, and dogs were trained to operate the touchscreen device by a step-by-step procedure using food reward but no aversive stimulus. Early on during training, owners could actively “explain” to their dogs what to do and comfort the animal in case of failure (i.e., no reward situations), to avoid loss of motivation and make the situation more similar to other training contexts. After dogs learned to respond to the Go stimulus by executing a nose poke, they were presented with the Go and No-Go stimuli simultaneously and trained to respond only to the Go stimulus. Dogs were rewarded with a treat and praise/stroke for every correct Go response but received no negative feedback for omission or commission errors. During the final phase of training, dogs were presented either with the Go or the No-Go stimulus and were rewarded for every correct No-Go response, with the time between stimulus onset and food reward gradually increased until it reached 3 s (the preset time window) to make the relatively long inhibition period less frustrating.

As the dog was recently proposed to be a promising model species to study the evolutionary background of certain human sociocognitive skills, comparative studies aim to apply similar research tools across species. Given that in humans, behavioral disinhibition is associated with personality and ADHD features, the authors of a recent study aimed to examine the associations between family dogs’ performance on a behavioral GNG paradigm and their owner-reported personality and inattention and hyperactivity/impulsivity scores (Bunford et al. 2019a). A greater proportion of commission errors was associated with greater hyperactivity/impulsivity, in accordance with what has been found in humans. Regardless of accuracy, greater confidence and extraversion and lower openness were linked to shorter RTs to correct Go responses and commission errors, and greater inattention was associated with shorter latency to commission errors.

With a diverse set of tasks and tools applied, cognitive biases have been observed in a range

of nonhuman animal species (e.g., Kis et al. 2015). Discrimination tasks are one effective method for probing cognitive bias in animals, however, a GNG procedure necessitating active choice in response to ambiguous stimuli could also be applied efficiently. In studies with discrimination tasks, animals' inner states are typically experimentally manipulated to induce cognitive bias. In one study, to assess if negative emotion induction (being housed under unstable vs. stable conditions) leads to negative bias in rats, a GNG task was applied; subjects were trained to press a lever to the Go stimulus to obtain a food reward and to withhold this behavior in response to the No-Go stimulus and avoid a burst of aversive white noise. Rats housed in a chronically stressful environment responded less quickly and frequently both to Go and to ambiguous stimuli, indicating less optimism (Harding et al. 2004).

Recently, in dogs, to assess the link between personality and naturally occurring individual differences in cognitive biases was examined (Bunford et al. 2019b). The study established a relationship between a behavioral index of more positive/negative judgments about ambiguous stimuli in a modified Go/No-Go paradigm and individual differences in owner reported personality; dogs with higher conscientiousness and extraversion scores were more likely to exhibit a Go response to ambiguous stimuli.

Despite the many advantages of the GNG procedure, there are also limitations of the method in comparative studies. Considerable pretraining is necessary, differences in food motivation can have a confounding effect, and the paradigm may not be useable in case of some focus populations, such as for example, in dogs with extreme traits such as having high scores on ADHD-like symptoms.

## Conclusions

The GNG procedure is a simple experimental set up that is especially efficient in assessing some important sociocognitive abilities of humans and nonhuman animals such as response inhibition

and cognitive bias. Analyzing the number and proportion of the two types of errors (commission and omission errors) and the RT for go responses can contribute to important discoveries about the relations between functions such as behavioral response inhibition, attention or temperament in different species and help establish, in comparative studies, boundaries of comparability for modeling human inhibition and other characteristics of which inhibition is part.

## Goal

José E. Burgos and Jonathan Buritica  
Centro de Estudios e Investigaciones en  
Comportamiento, University of Guadalajara,  
Guadalajara, Jalisco, Mexico

## Synonyms

Aim; Objective; Purpose; Target

Like many other terms in psychology (e.g., see “Drive State,” this volume), “goal” is a term from ordinary language. In the Oxford English Dictionary (<https://en.oxforddictionaries.com/definition/goal>), the following ordinary meaning of “goal” is found (among others): “The object of a person’s ambition or effort; an aim or desired result.” Psychologists’ uses of “goal” adopt and elaborate on this ordinary meaning, where by “goal” they mean a kind of mental state that “guides” certain actions conducive to reaching the goal. Roughly equivalent terms are “purpose” and “aim.” A term that often accompanies talk of goals is “outcome,” an end-product or result of actions that are guided by the goal.

Somewhat more technically, but perhaps less intuitively, most psychologists (except for Skinnerians) view goals “as internal representations of desired states, where states are broadly construed as outcomes, events, or processes” (e.g., Austin and Vancouver 1996, p. 338), where “internal” usually means “mental” (and vice versa). A mentally represented outcome is an expected or *thought-of possible* result of certain thought-of actions. If the thought-of actions actually occur, the thought-of results may or may not actually occur. If they do, the goal is said to have been achieved.

This view is consistent with a defining feature goals share with other mental states such as expectancies, desires, needs, wants, wishes, and beliefs. Philosophers of mind call this feature “intentionality,” from the Latin noun “intentio” and verb “intendere,” meaning “to point to” or “to aim

at.” The notion was introduced by the Medieval Scholastics and revived by philosopher/psychologist Franz Brentano in his 1874 *Psychology from an empirical standpoint* (originally published in German, and translated into several other languages).

Intentionality is the property of “being about,” “being directed towards,” or “referring to” something. In more contemporary lingo, intentional states have *representational content*, or are *propositional attitudes*. Paradigmatic examples are beliefs, which makes them essentially similar to goals. All beliefs are about something, and this is their distinctive feature. For example, the belief *that* it is raining is about rain, where the term “that” is used as a function word to indicate the subject or object (rain) of verb (believing). The term “that” here thus indicates a direction, pointing to or aiming at something, the object of an intentional state (in the case of this belief, rain). However, the object of this belief is not the actual physical rain occurring externally, independently of the mind, but a mental representation of rain.

In general, Brentano maintained that an intentional state’s object (that about which the state is) was *constitutive* of or *existed in*, and hence it was as mental as, the state itself. The object is a mental representation *of* (not about) something external to the state. The belief that it is raining is about a mental representation of rain, not about the actual physical rain, *even if it is being witnessed*. If not (perhaps someone said it was raining), the mental representation which is the object of the belief cannot be of that particular rain, but of something else, most likely of previously experienced rains.

This distinction becomes clearer in the belief that it *will* rain tomorrow. Evidently, this belief cannot be about tomorrow’s rain. It seems incoherent to say that a mental representation represents (literally, “presents again”) a future event. What is represented in that belief must be something else, most likely, previously experienced rains. If the believer has never experienced rain before, the belief would be about some previously experienced verbal description, painting, or photograph of rain.

The same clarification applies to goals: The goal to get a college degree is not about some yet-to-occur future state that exists nonmentally, independently of and external to the goal. Rather, the goal is about a mental representation of something, a representation that exists in the present and only mentally, as part of the goal *qua* mental state. This something could be a variety of previous experiences (e.g., photographs or videos of people obtaining their degree, verbal descriptions of the advantages of getting a degree, photographs of actual college degrees obtained by other people, etc.), which are external to the goal and its object. This clarification avoids the absurdity that goals are determined by something in the physical future, which violates the venerable but still valid principle that the physical future cannot cause the physical present.

In theorizing about goals, psychologists often speak of “goal-oriented behavior” to refer to actions that are guided by goals *qua* mental representations (see Aarts and Elliot 2012, for a recent compilation). But then again, goal-oriented behavior is not determined by the yet-unachieved goal in the physical future. The mental representation, the object of the goal, can only be of some previous experience (e.g., having achieved a goal in the past, tales of others having achieved goals and their perks, etc.).

A desired outcome is also often said to be “anticipated” or “expected.” But how do outcomes come to be expected? Answers have revolved around the conjecture that *learning* is key to goal-formation and pursuit. During 1920s and 1940s, classical learning psychologists based their answers on observations of subjects, typically hungry rats, that learned to navigate mazes (typically T mazes) from a starting area to a finish or “goal” area with a reward in it (typically food). The more precise question here is this: How do rats learn to anticipate that navigating a maze in a certain way will allow them to reach the finish box and obtain the reward without sensing any of it from the starting box? This question, in contrast to the ordinary definition of “goal” given at the

beginning, admits the possibility of goals in non-human animals.

Hull (1930), an influential classical learning theorist, called this ability “foresight,” “*the reaction to an event which may be impending, but which has not as yet taken place*” (p. 514). But then again, it is incoherent to say that the rat reacts in the present to a future event (obtaining the food). Whatever the rat reacts to must reside in the present and/or the past. Hull hypothesized that sufficient experience with obtaining food in the finish box by navigating a maze in a certain way promoted the strengthening of *stimulus-response* (S-R) associations. The Ss were the maze’s various exteroceptive cues (e.g., visual, auditory, olfactory, tactile), and the animal’s proprioceptive cues. The Rs were the rat’s various movements through the maze.

Hull (1943) also submitted his “goal-gradient” hypothesis. According to this hypothesis, the S-R associations grew progressively stronger as the animal approached the finish box, after sufficient experience with obtaining food at the end of the maze for navigating it in a certain way, which Hull viewed as “reinforcing” S-R associations. Hull thus conceived goals as chains of S-R associations that progressively led the animal from the start to the finish box. Rather than unanalyzable, elementary constructs, Hull (1943) viewed goals as “emergents” (p. 29) that could be derived from more elementary postulates about stimuli, responses, and their associations.

Hull proposed that *need reduction*, discussed in another entry (see “[Need Reduction](#)”), was the reinforcement mechanism in maze learning. His theorizing was molecularist in that he viewed particular responses as the proper units of analysis of goal-seeking behavior. Tolman’s (1948) “purposive behaviorism,” in contrast, was *molarist* in that he viewed *acts*, long response chains, as the proper units of analysis of goal-seeking behavior. He further hypothesized that maze learning consisted in the formation of “cognitive maps” as mental representations of all the maze’s relevant spatial locations and their relative positions.

More recently, goal-directed behavior has been studied using operant conditioning chambers,

where the reward is given in a food receptacle that the animal must approach to obtain the reward. Unlike mazes, operant conditioning chambers have no paths that the animal must learn to reach the site of the reward. Animals in this apparatus have been observed to approach and engage with the site of the reward. Boakes (1977) called this behavior “goal-tracking” and defined it as behavior directed towards the location of the reward.

Typically, obtaining the reward in an operant conditioning chamber also requires a so-called instrumental response (e.g., pressing a bar in rats), which could be viewed as part of a goal-directed behavior. Some researchers have studied whether this response is affected by changes in the value of the reward. For example, Colwill and Rescorla (1985) trained rats in an operant conditioning chamber to obtain two rewards, each one dependent on a different response topography (bar-pressing vs. chain-pulling). Then, one reward was devalued through association with either illness induced by LiCl, or satiation. In a test, both instrumental responses were measured. The results showed a significant reduction in the rate of the response that had been associated to the devalued reward. This result suggests that goal-directed behavior is sensitive to S-outcome relations.

Some researchers (e.g., Dolan and Dayan 2013) also distinguish habits from goal-oriented behavior. On this distinction, a habit is automatic and insensitive to changes in the value of the reward, whereas goal-oriented behavior is directed towards reaching a reward and modifiable by such changes. This distinction is consistent with evidence that instrumental behavior trained for a long time is significantly less sensitive to changes in reward value than instrumental behavior trained for a shorter time (Adams 1982).

Others have used this distinction to explain the transition from recreational to abusive substance drug consumption (for a review, see Hogarth et al. 2013). A drug’s initially high value (due to its novelty) would explain the initial consumption (goal-oriented behavior) as involving action-outcome associations. Initial drug-seeking is goal-directed behavior determined by the drug’s

anticipated incentive value. When the drug is consumed for the first few times, it reinforces in an instrumental way the drug-seeking behavior, promoting the formation of an R-outcome association. After more extended drug consumption, chronic (abusive) consumption (habit) promotes the formation of S-R and S-outcome associations which maintain persistent drug seeking that becomes independent of the drug's initial incentive value.

Despite important theoretical and conceptual differences, most psychologists agree that brain functioning and structure are key to all behavior, goal-seeking behavior included (Hull famously cast his theory explicitly in neural terms, using expressions like “neural reactions,” “neural impulses,” “neural mediation,” and “neural activity”). Some brain regions have been linked to goal-directed behavior. For example, lesions in the medial prefrontal cortex (e.g., Ostlund and Balleine 2005) disrupt acquisition but not maintenance of reward-seeking behavior controlled by instrumental contingencies. This result and others support the view that goals as mental representations may be more profitably viewed as neural representations (activation patterns) in certain brain areas.

## Goggles Experiment

Martin Schmelz

Department of Cognitive Biology, University of Vienna, Vienna, Austria

The goggles experiment is the common name of an experimental procedure proposed by Cecilia Heyes (1998) with the aim of distinguishing the theory of mind hypothesis of behavior from non-mentalist alternatives. The theory of mind hypothesis claims that nonhuman animals, most

notably chimpanzees and other primates, have a concept of mental states like “see,” “want,” or “know” (Premack and Woodruff 1978). Heyes’ objection was that all experiments and observations supporting this claim could also be interpreted with alternative explanations like associative learning or inferences that did not require mental state attribution.

The original goggles experiment is based on a guesser-knower paradigm (Povinelli et al. 1990), and the procedure consists of three phases:

1. In the *pre-training*, chimpanzees would be trained to wear two pairs of goggles that are only distinguishable from the outside by an arbitrary cue like different rim colors. Only by wearing the goggles, chimpanzees would experience that one pair is opaque while the other is translucent. They would never experience anybody else wearing the goggles at this point.
2. In the *training*, chimpanzees would watch an experimenter hiding food underneath cups behind an occluder. One trainer would be present for the baiting, while a second trainer would leave the room and come back after the baiting. Both would then indicate one of the cups, and chimpanzees are rewarded for choosing the cup indicated by the trainer who saw the baiting (the knower) and never for choosing the cup indicated by the one who left the room (the guesser).
3. In *transfer*, training trials would be interspersed with probe trials in which both trainers remain in the room but wear the pairs of goggles from the pre-training. In this case, the trainer wearing the translucent goggles would be the knower and therefore the right choice if chimpanzees have a concept of seeing. Importantly, chimpanzees would not be rewarded differentially in probe trials to avoid associative learning.

Heyes argued that if chimpanzees take the knower’s cues in probe trials more often than the guesser’s, it would distinguish between the theory of mind hypothesis and non-mentalist alternatives

as it can only be based on using their own mental experience to infer the others’ mental states.

Other variations of the goggles experiment have been proposed. Povinelli and Vonk (2003) suggested simplifying the procedure in a way that does not involve the extra step of distinguishing between knowing and guessing. In this version, chimpanzees can choose to beg for food between two experimenters—one wearing an opaque bucket over their head and one wearing a translucent one. If the chimpanzees preferentially gestured to the latter, it would show that they understand who can and who cannot see them.

In general, a “goggles experiment” has to follow the basic structure of (1) experiencing the properties of unknown eye covers that cannot be inferred from the outside and can only be distinguished by an arbitrary cue and (2) transferring this experience to a novel situation in which others look through these covers and make inferences about their mental states.

Recently, a study based on this general structure has been conducted with chimpanzees with positive results and has therefore been suggested to support the claim of mental state attribution in chimpanzees (Karg et al. 2015). However, the interpretation of these and other results supporting the theory of mind hypothesis in nonhuman animals, including primates and corvids, still remains a debated topic of animal cognition.

## Gonochorism

Andrew M. Holub and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

Dioecy; Gonochory; Unisexualism

## Definition

Gonochorism is the condition of individual organisms within a species existing as one of two possible sexes, specifically male or female. Gonochorism includes distinct sex-specific reproductive strategies among sexual reproducing taxa.

## Sex in the Animal Kingdom

Within the kingdom Animalia, sexual reproduction is the norm, and asexual reproduction appears as a rare exception, and usually not in exclusion, to sexual reproduction (Avisé 2008; Schön et al. 2009). Gonochorism is likewise characteristic of the vast majority of animal species (Jarne and Auld 2006) and is almost ubiquitous among

vertebrates, with the largest variations occurring among marine organisms, especially teleost fish (e.g., Kobayashi et al. 2013). Compared to asexual reproduction, sexual reproduction necessitates the combination of gametes from two different individuals. In all known animal taxa, sexual reproduction occurs through the combination of heterogenous gametes that differ in size and shape, a condition known as anisogamy (see Kumar et al. 2019). Indeed, anisogamy appears to be common because of the costs associated with isogamy, in which gametes of all individuals are of similar size and shape (Matsuda and Abrams 1999).

The size of the gametes is the most direct means of differentiating between sexes. By definition, male gametes are smaller, and female gametes are larger (see Verma 2019). Individuals producing smaller gametes are defined as males, and individuals producing larger gametes are defined as female. Sex determination mechanisms are more stable among mammals and birds and far more variable among many marine taxa, with genes, environment, and epigenetics determining and reversing sex across numerous gonochoristic fish species (see Baroiller and D’Cotta 2016). However, it should be noted that male and female sex are more usefully defined by reproductive strategy, rather than by immutable physiological characteristics (Schärer 2017). In this way, males and females occupy distinct reproductive niches that reflect the combination of their asymmetrical gametes and results in a cascade of sex differences, such as in morphology and behavior (see Eberhard 1996; Trivers 1972).

Gonochorism can be contrasted to simultaneous hermaphroditism, which is the capacity of an individual to reproduce using either male or female gametes within its lifetime (see Rosenfield 2018). Not infrequently within simultaneous hermaphroditic species, such as marine flatworms (*Pseudoceros bifurcus*; Michiels and Newman 1998), individuals may preferentially attempt to reproduce using less costly male gametes and attempt to avoid reproducing using more costly female gametes (Michiels and Koene 2006). These species are not considered gonochoristic even though they demonstrate a preferred

sex-specific reproductive strategy, because they maintain the capacity to reproduce using male or female gametes. Sequential hermaphroditism also is a separate reproductive strategy from gonochorism, although there is some overlap such that it may be unclear whether a species is gonochoristic or sequentially hermaphroditic (e.g., *Patella ferruginea*; Espinosa et al. 2009). For sequential hermaphroditic species, individuals may change sex across the lifespan but only conserve one sex-specific reproductive capability at a time. For example, an individual of a protogynous species, such as the rock wrasse (*Halichoeres semicinctus*; Adreani and Allen 2008) may begin life producing exclusively female gametes but may undergo a transformation later in life after which it will only produce male gametes. In these cases, the individuals may appear to be gonochoristic, but because it is possible for a female to develop a male reproductive capacity, such taxa are distinct from gonochorism. Gonochorism conveys distinct benefits compared to hermaphroditism and asexual reproduction, which likely have acted as selection pressures favoring the reproductive strategy, but more data are needed to specify the evolutionary trajectory of gonochorism in the animal kingdom (Sasson and Ryan 2017).

## Gordon Burghardt

Gordon M. Burghardt  
University of Tennessee, Knoxville,  
TN, USA

**Gordon M. Burghardt** is an Alumni Distinguished Service Professor in the departments of Psychology and Ecology & Evolutionary Biology at the University of Tennessee. He has broad interests in many aspects of animal behavior, publishing widely in several areas.

## Early Life and Educational Background

Dr. Burghardt was born on October 11, 1941 in Milwaukee, Wisconsin; he spent his early life there in the public schools, wandering in parks and fields, and attending summer camps on the many lakes in the southeast Wisconsin. Here, he nurtured his love of the natural world, especially snakes and other reptiles. Pet animals included turtles, lizards, and snakes, along with a budgerigar, raccoon, skunk, and others. He attended the University of Chicago and, although initially majoring in chemistry, received both his undergraduate and PhD degrees in biopsychology in 1963 and 1966, respectively. His most important mentor was Eckhard H. Hess who was one of the few American comparative psychologists engaged in ethological approaches to animal behavior at that time and who had close contacts with many European ethologists. Hess, though primarily working with birds and humans, encouraged his work on reptile behavioral development and chemoreception.

## Professional Career

After completing his PhD, Burghardt remained at the University of Chicago as an Instructor in Biology but in 1968 gave up a tenure track position to accept a position at the University of Tennessee in Knoxville, where William S. Verplanck, also an experimental psychologist promoting ethology, was building an impressive psychology department. Burghardt thought that getting closer to field settings and national parks and forests was beneficial after spending his life primarily in large cities. Except for professional leaves and visiting fellowships, he has remained at the University of Tennessee for over 50 years. These 50 years have seen many serpentine shifts in research topics, but his core interests remained the same and he has returned to some after a 20–30 year hiatus!

Over his career, he is very proud of the over 40 graduate students he has mentored and the development of many of their careers and accomplishments. They have gone in many different directions, which in some ways mirrors the many areas of research Burghardt has explored. Over the years, Burghardt has been active with several professional organizations and editorships. He hosted the annual meeting of the Animal Behavior Society in Knoxville in 1981, and later that decade was elected to several offices in the society, including President. More recently, he served as President of the Society for Behavioral Neuroscience and Comparative Psychology (Div. 6, APA) and received the Clifford T. Morgan Distinguished Service Award. He also developed and directed the Life Sciences Graduate Program in Ethology at the University of Tennessee. He has edited or been associate editor of several journals including *Ethology*, *Animal Learning and Behavior*, and the *Journal of Comparative Psychology* and served on many editorial boards. He is a Fellow of the American Psychological Association, Association for Psychological Science, AAAS, and the Animal Behavior Society, and received many local awards at the University of Tennessee, including the Macebearer award, the highest academic award for faculty members. Burghardt has published hundreds of journal articles, book chapters, and book reviews as well as having written or

edited seven books, including, most recently, as an Associate Editor of the 80 chapter two volume APA Handbook of Comparative Psychology (2017).

## Research Interests

Burghardt has always been interested in understanding the natural behavior of animals and all his work reflects variations of this focus. His early work was on the ontogeny of food preferences and the role of sensory cues in prey detection and selection, primarily in snapping turtles, natricine snakes, and small lizards. Upon arriving in Tennessee, where few psychology students saw reptiles as useful research subjects, the administrators of the nearby Great Smoky Mountains National Park were having to deal with escalating problems with black bears such as bear jams on the roads, tourists feeding bears, and bears wandering into picnic areas and commandeering culinary resources. He brought Park Superintendent Fry and his staff to UT to give a joint Zoology-Psychology talk and then meetings on developing a collaborative research program. This is still ongoing. Burghardt's role was getting some field observations of bear-human interactions underway with students but within a few months two orphaned bear cubs needed to be cared for, so Burghardt raised them in his house and applied for a small NIMH grant to build a research enclosure in the park. This resulted in research theses by several students in which the fine vision bears have, including color, was established along with basic information on foraging, food preferences, play, agonism, mating, learning, and so on. After many years, Burghardt is again studying bear cub behavior through analyzing den cam videos of the first months of life in natural dens of wild black bears in Minnesota with Lynn Rogers.

Burghardt, as a high school student, joined the American Society of Ichthyologists and Herpetologists (ASIH) and is a life member. All during his career at Tennessee he has continued reptile behavior research in several areas besides snake chemoreception including comparative and ontogenetic studies of constriction, antipredator

behavior, sexual dimorphism, conservation genetics, environmental enrichment, optimal foraging in monitor lizards, effects of diet on behavioral and morphological plasticity, multiple paternity, behavior of two-headed snakes, and other topics. After meeting A. Stanley Rand, scientist at the Smithsonian Tropical Research Institute in Panama, and hearing about the remarkable communal nesting behavior of green iguanas, he teamed up with Stan to study what happened during hatching, nest emergence, and their subsequent life. They discovered remarkable sociality in the hatchlings then viewed as unconceivable in a lizard. This work led to many studies with students and colleagues as well as an edited book. Again, although his main fieldwork ended over 35 years ago, he and former students are still mining important information from the data collected. Two documentaries depict this research.

Another collaborative research program began with a Japanese reptile ethologist, Akira Mori, at Kyoto University studying an unusual snake with two methods of delivering toxins. The snake is the Japanese Tiger Keelback and it is a rear-fanged animal so has a venom that can be dangerous, though the snake is generally not prone to bite. However, the species also has glands on the neck that contain toxic bufadienolides, cardio-tonic steroids sequestered from skin secretions of toads. Associated with these glands are unique defensive postures and behaviors not seen in species without such glands. Research on the biochemical, behavioral, anatomical, physiological, and ecological aspects of these animals has involved a multidisciplinary program of research with many colleagues. Burghardt has worked in Japan and Mori in the US on them. Snakes who do not eat the toads, as from toad-free islands, flee rather than deploy nuchal gland-related defensive behavior and, remarkably, snakes seem to "know" when they are defended by the toxins.

Reptile learning and cognition, including social learning (as in turtles), has also been a focus of his research and he has worked on this topic over much of his career. This focus on learning and sociality in reptiles along with the focus on development led to an interest in why reptiles do not seem to play. For many decades, he has

been studying play and many of his contributions are described in his 2005 book, *The Genesis of Animal Play: Testing the Limits*. He developed criteria for recognizing play in species and contexts where it had not been identified, documented the occurrence of play in a number of unusual species including turtles, lizards, crocodilians, cichlid fish, stingrays, and spiders, formulated a theory underlying play termed Surplus Resource Theory (SRT), developed hypotheses on the origin and evolution of play. He has also worked on phylogenetic modeling of play and SRT and has applied play concepts to creativity, religion, and ritualized behavior.

Although other empirical projects could be mentioned, Burghardt also has written extensively on ethical issues and especially on the early history of animal behavior, ethology, and comparative psychology. He has developed theoretical and conceptual ideas involving communication, critical anthropomorphism, controlled deprivation, and other topics. Besides Hess, Verplanck, Rand, and Mori noted above, the following senior people also were, along with others, extremely valuable at various times in his career: George Rabb, Charles C. Carpenter, Marc Bekoff, Carl Gans, Konrad Lorenz, and Brian Sutton-Smith. He was honored by a symposium on his career organized by former students at the 2014 annual joint meeting of the herpetological societies in Chattanooga, TN, hosted by the ASIH. The occasion was to recognize the 50 years since his first published scientific paper in 1964, a comparative study parsing the roles of prey size and movement in prey capture in lizards. His twin daughters, Karin and Liana, both now PhD biologists doing creative and important research themselves attended, and he is more proud of them than any of his scientific contributions!

## Gordon Gallup

Gordon G. Gallup

State University of New York at Albany, Albany, NY, USA

## Mirror Self-Recognition

In 1969, he conducted an experiment designed to determine if chimpanzees could recognize themselves in mirrors (Gallup 1970). Although chimpanzees initially respond to mirrors as though they were seeing other chimpanzees, after a couple of days the chimpanzees began to use the reflection to respond to themselves. As an objective test of self-recognition he developed the mark test, where anesthetized chimpanzees were marked with a red, odorless, nonirritating dye on the top half of an eyebrow ridge and the upper half of the opposite ear. Upon recovery from anesthesia, he discovered that the chimpanzees used the mirror to touch and investigate the red marks on their faces that could only be seen in the mirror.

These findings have been widely replicated with chimpanzees and extended to include orangutans and humans. Early attempts to adapt this methodology for use with children, however, were seriously flawed (Gallup 1994). The capacity for mirror self-recognition in other species is widely debated, but as yet the evidence is not conclusive (Anderson and Gallup 2015).

The mark test has been cited as the “gold standard” for assessing self-recognition, and it has survived multiple challenges, including the idea that it may be an artifact of species differences in face

touching behavior (Suarez and Gallup 1986) or an artifact of anesthetization (Povinelli et al. 1997), along with claims that failures to find self-recognition may be due to gaze aversion (Anderson and Roeder 1989), a lack of interest in superimposed body marks (Gallup et al. 1980), or that the presence of a human researcher may inhibit or distract subjects from investigating the marks (Shillito et al. 1999). Pervasive species differences in mirror self-recognition continue to prevail in spite of attempts to argue for the possibility of self-recognition in other modalities (Platek et al. 2004), along with repeated but unconvincing attempts to engineer self-recognition in other species (Anderson and Gallup 2015) and unsupported claims that self-recognition has nothing to do with self-awareness (Gallup et al. 2014).

More recently, Platek and Gallup developed a method for assessing self-recognition that involves showing people faces on a computer monitor, and they are instructed to press particular keys on the keyboard to indicate if it is a stranger's face, a familiar face, or their own face (Platek et al. 2004). Rather than an all or none (pass/fail) approach to self-recognition, this paradigm can be used to quantify individual differences in self-face identification latencies measured in milliseconds and that has led to some striking results implicating important and clinically relevant self-processing deficits (Platek et al. 2003).

Gallup's idea that self-awareness may be a springboard to being able to use your experience to model the experiences of others and make inferences about their mental states has also been controversial (Gallup 1982). The jury is still out about mental state attribution in chimpanzees and orangutans (Shillito et al. 2005), but for humans there are no documented instances of being able to take into account what others know, want, or intend to do without being able to recognize yourself. Likewise, deficits and developmental delays in self-recognition (e.g., autism) covary with mental state attribution deficits, and this also holds true for brain-damaged patients who are deficient in self-recognition as well as those who lose the capacity to recognize themselves due to mental illness (Gallup et al. 2003).

## Tonic Immobility and Open Field Behavior

Tonic immobility is triggered by the application of manual restraint, such as holding an animal down on a flat surface. Initially the animal will struggle and try to escape, but if you persist in holding the animal in place for several seconds it will go into a seemingly catatonic-like state of physical immobility which can last from a few minutes to over an hour or more after you remove your hands.

In a series of studies featuring many different species, Gallup and his students showed that laboratory procedures designed to increase fear (e.g., loud noise, conditioned aversive stimuli) prolong the response, while those that alleviate fear (e.g., handling, taming, tranquilizers) antagonize the reaction. Under natural conditions, the evidence shows that tonic immobility is one of several defensive reactions in a distance-dependent series of antipredator strategies (Gallup 1977). Tonic immobility depends on the integrity of neurological structures at the level of the brainstem, is associated with widespread autonomic involvement, and the duration of the response is related to changes in brain serotonin (Wallnau and Gallup 1977).

Examples of extreme behavioral inhibition in humans prompted Suarez and Gallup (1979) to theorize that "rape-induced paralysis" may be an instance of tonic immobility. As a result, the idea that certain states of behavioral inhibition in humans (e.g., rape, PTSD, catatonic schizophrenia) represent instances of tonic immobility has been embraced by a growing number of clinical psychologists (Marx et al. 2008). Tonic immobility is a useful means of modeling states of extreme behavioral inhibition under controlled laboratory conditions and may have important practical implications for how such states are dealt with in applied settings (Gallup and Rager 1996).

As an extension of this predator-prey model, Gallup undertook a series of studies to re-examine open field behavior. The point of departure for these studies was that what animals do when tested in an open field is a byproduct of predatory overtones associated with being contacted, handled, and tested by a human experimenter and also being socially separated from companions. This

creates a classic approach/avoidance conflict, and predictions derived from this model are surprisingly accurate across a number of mammalian and avian species.

For example, the mere presence of someone in the room when animals are tested makes animals freeze longer. The further away the experimenter is from the open field and if the subjects cannot see his/her face the amount of time spent freezing diminishes. Likewise, animals that are placed by hand into the open field freeze longer than those that are mechanically introduced into the open field. According to this model, the initiation of movement in the open field represents an attempt to reinstate contact with companions. Consistent with this analysis, animals that are tested in pairs wait longer to begin moving and show fewer attempts to escape from the open field. In contrast, animals maintained in social isolation before testing wait longer to move (Gallup and Suarez 1980; Suarez and Gallup 1981, 1982).

Results such as these raise serious questions about the validity of open field testing as it has been traditionally used as a measure of emotionality.

## Human Reproductive Competition

In the 1980s, Gallup's attention began to focus on human behavior from an evolutionary perspective. Rather than being a matter of competition for scarce resources and the survival of the fittest, evolution is a matter of competition for gaining genetic representation in subsequent generations.

Work that Gallup and others have done that was inspired by this perspective has shown that the mere sound of a person's voice contains information about their sex, age, health, fertility, body configuration, facial attractiveness, grip strength, when they lost their virginity, how many sex partners they have had, their propensity for infidelity, and where they are in their menstrual cycle (for a review see Gallup and Frederick 2010).

Work from his lab has also shown that most people have found themselves attracted to someone only to discover that, after they kiss that person, they are no longer interested (Hughes et

al. 2007). Thus, there may be hard-wired mechanisms activated at the moment of the first kiss that function to make a determination about whether this would be a good genetic/reproductive match. Sex is also a component to courtship, and sampling semen from different suitors may be analogous to kissing; i.e., either you wake up the next day head over heels in love or with feelings of regret for what you did the night before (Gallup and Reynolds 2014).

Most women have a guarantee of sharing half of their genes in common with their children. But, because of female infidelity, men have to contend with paternal uncertainty and the prospect of being cuckolded. Gallup's work on paternal assurance tactics has shown that men invest in children in relation to the presence of shared physical and psychological features (Gallup et al. 2016). Competition for paternity has even affected human genital morphology. Using laboratory simulations Gallup and his students have shown that the peculiar shape of the human penis evolved to compete with the presence of rival male semen in the woman's reproductive tract by promoting semen displacement and increasing the likelihood of paternity by the resident male (Gallup et al. 2003). This research prompted Satoshi Kanazawa to conclude that "if you want to know what women have been up to, look at the human penis." The work on human genital morphology also led Gallup to raise the question among uncircumcised men of unwittingly piggybacking rival male semen captured under the foreskin from one vagina to the next (Gallup and Burch 2004), which inspired a recent novel "The Hitchhiker's Child" (Baker 2013).

As evidence for the impact of some of this work, it is worth noting that in 2017 the journal *Evolutionary Behavioral Sciences* published by the American Psychological Association listed seven of his former students as members of the editorial board (Rebecca Burch, Michael Frederick, Andrew Gallup, Marissa Harrison, Susan Hughes, Nathan Pipitone, and Steven Platek).

Some of Gallup's more controversial work on reproductive competition involves applying evolutionary theory to homosexuality (Gallup and Suarez 1982) and attitudes toward homosexuals (Gallup 1995). According to him, homosexuality

is a byproduct of evolved differences between men and women in fitness maximization strategies and as a consequence everyone has the capacity to become homosexual. Likewise, his view of homophobia as a byproduct of natural selection implies that everyone (including homosexuals) will exhibit homophobia under certain conditions.

## Yawning as a Brain Cooling Mechanism

While most of Gallup's research continues to focus on human reproductive competition about 10 years ago he became interested in yawning, which is something we all do but was not well understood. In contemplating what happens during the execution of a yawn, it occurred to him that yawning might function as an evolved brain cooling mechanism.

Just as is true for metabolism elsewhere in the body, brain metabolism generates heat and research had shown that one of the rate-limiting steps to how big brains can get is dependent upon the development of mechanisms that function to dissipate heat and cool the brain (Falk 1990). As evidence for the idea that yawning may be one of several mechanisms that function to maintain thermal homeostasis in the central nervous system, Gallup and his son Andrew found that nasal breathing and forehead cooling antagonizes yawning in college students (Gallup and Gallup 2007). They also found that rats with temperature probes implanted in the frontal cortex exhibited consistent increases in brain temperature prior to yawning, with brain temperature returning to baseline within seconds after the execution of a yawn (Shoup et al. 2010). Additional work has confirmed the existence of a thermal window that constrains yawning at ambient temperatures that rise to body temperature or approach freezing (Gallup and Eldakar 2013). A recent comparative study inspired by Andrew Gallup found positive correlations that exceeded .9 between species differences in yawn duration and both brain weight and number of cortical neurons (Gallup et al. 2016). As brains get bigger yawns last longer.

Numerous medical problems are related to thermoregulation (e.g., multiple sclerosis) and

emerging evidence suggests that excessive yawning in humans may be a diagnostic red flag for central nervous system thermoregulatory dysfunction (Gallup and Gallup 2008).

Contrary to popular opinion, yawning is a compliment. Because yawns appear to function to cool metabolically overheated brains, if someone yawns the next time you are talking with them do not take it as an insult. Rather than a sign of boredom, yawning is an indication that mechanisms have been activated to maintain attention and promote optimal cognitive processing.

Other aspects of Gallup's research are also related to thermoregulation. His work with Jessica Ash on the impact of climate change on brain evolution suggests that global warming may be undermining the conditions that gave rise to big human brains during the last ice age (Ash and Gallup 2007). And because the scrotum functions to cool the testicles, he has theorized that descended testicles evolved to capitalize on the conditional increase to body temperature that occurs when sperm are released into the vagina which functions to induce a time-bound activation of sperm (Gallup et al. 2009).

It should be clear from this brief overview that rather than being focused and pedantic, Gallup's interests have been very broad and driven by theory construction and hypothesis testing. One of his least cited but most interesting papers involves our reliance on visual metaphors to capture different mental states, which may be a byproduct of our earlier adaptation to life in the trees as arboreal primates (Gallup and Cameron 1992).

**Gordon G. Gallup, Jr** was born in 1941 and held his first faculty appointment in 1967 as an Instructor at Washington State University, where he got his Ph.D. in 1968. In the fall of that year, he accepted a position at Tulane University where he was promoted from Assistant to Associate Professor in 1972 and to Full Professor in 1974. In 1975, he took a position at the State University of New York at Albany as Chair of the Psychology Department and served in that capacity for three consecutive 3-year terms. He continues to hold a position there as a faculty member. He served as the Editor of the **Journal of Comparative Psychology** from 1989 to 1994.

Most of Gallup's research has focused on the impact of evolution on behavior. Some aspects of his research are represented by work on the following four broad but not mutually exclusive categories.

## Goshawk

### ► Accipiters

## Graded Signals

## Synonyms

### Continuous signal

## Definition of Graded Signals and Some Clarifying Examples

Signal variants, and signalling repertoires, can be described as either graded or discrete, though categorizing signals as such is often challenging and ambiguities often exist (Keenan et al. 2013; Wadewitz et al. 2015). Graded signals are those whose magnitude can vary continuously; the signal can take any value from a continuous distribution, with intermediate signal values between any two values being possible (Bradbury and Vehrencamp 1998; Marler 1975). As signals have evolved to influence the behaviour of receivers, for a signal to be considered graded, receivers must also be able to perceive signal variation as meaningful and use this variation to adjust their responses (Marler 1977; Fischer et al. 2001). Conversely, discrete signals can only take a finite number of values; intermediate values do not occur or, at least, are not perceived by receivers as meaningful, meaning that receivers perceive signal variants as qualitatively different (Bradbury and Vehrencamp 1998; Marler 1975).

Though static signals which exhibit continuous variation among individuals in a population are sometimes referred to as “graded” in the literature (Rowland et al. 1995), the label “graded” typically applies to dynamic signals within a species’ signalling repertoire that communicate something about the immediate circumstances of the signaller, such as how motivated the signaller is at that moment to attack, or the level of threat posed by a predator. An example of a graded signal is provided by warning signals given by reed warblers in response to threats to their nest. Mobbing calls were given in response to sparrowhawks and cuckoos at faster rates when threats were detected closer to the nest, i.e., when the threat was more immediate (Welbergen and Davies 2008). Additionally, mobbing calls given at faster rates elicited a greater response from conspecifics, with a greater number coming to the signaller’s aid. This demonstrates that this signal (call rate) is sensitive to immediate conditions in a graded way, and receiver responses (probability of approaching and aiding the signaller) are sensitive to graded variation in signal magnitude.

Continuous variation in many animal signals can be perceived and acted upon by receivers, but not all signals exhibiting continuous variation are typically referred to as graded. For example, in koalas, larger males produce bellows with lower-formant values, and females prefer these lower-formant bellows (Charlton et al. 2012). This suggests females use continuous variation in bellow characteristics among males to select for larger males. However, this should not be referred to as a graded signal, since anatomical constraints prevent individuals from producing a varied range of signal magnitudes. Typically, in signals considered graded, all individuals can and do flexibly express a broad range of these signals, and signal variation is not constrained by signal costs or anatomical constraints. When considering the reed warblers again, there is no indication that mobbing call rate is constrained such that only some individuals can call at certain salient rates.

### When Are Graded Signals Beneficial?

A primary benefit of using graded signals rather than discrete is that they enable animals to flexibly encode fine-grained information about the state of the world. For example, as demonstrated with the reed warbler example mentioned above (Welbergen and Davies 2008), rather than simply alerting conspecifics to the presence of an enemy, the graded dimension of the signal enables transmission of additional information regarding how serious and immediate a threat the enemy poses. This allows receivers to make more informed decisions about their participation in mobbing. Additionally, the nature of the states of the world that signallers are informing receivers about will influence whether graded signals are beneficial. For example, discrete calls are often associated with predator calls relaying information about the detection of specific predator types (Blumstein 1999). As such, the information being transmitted refers to real discrete categories in the world, making discrete calls effective. However, when communicating information about continuous states of the world (e.g., signaller arousal state or perceived urgency of a situation), graded

signals are often beneficial (but see Morris 1957; Johnstone 1994).

The flexibility afforded by graded signals may be useful in social interactions, which consist of an interplay of both interactants' signals. Graded signals allow a degree of temporal updating within a single signal type, allowing interactants to perceive and adapt to changes in one another's states in real time. In this way, they allow individuals to flexibly and gradually navigate interactions by probing one another's responses. For example, male satin bowerbirds perform vigorous courtship displays to females at their bowers, and females prefer more vigorously displaying males. However, if displays are performed too vigorously early on in the encounter, females become startled and flee (Patricelli et al. 2006). Females signal their level of comfort with a male's display intensity through crouching behaviour, with increasing crouching rates indicating a decreasing likelihood of being startled by intense displays. Males modulate the intensity of their displays in response to female crouching rates, facilitating gradual escalation of display intensity over the course of the interaction and so avoiding startling females (Patricelli et al. 2006). This example demonstrates the utility of graded signals in allowing social situations to be navigated in a flexible manner, and such flexibility can be beneficial in many contexts, including affiliative and aggressive interactions (Maynard-Smith 1982).

Graded signals also have the benefit that they can, at least partially, resolve trade-offs resulting from the need to manage different receivers at a single point in time. Optimal signal characteristics for evoking desired responses from different classes of receiver may be mutually exclusive, but in a graded signalling system, intermediate signals are possible which can allow a degree of success in managing both receiver types simultaneously. For example, in African painted reed frogs, males produce both advertisement calls and aggressive calls (Grafe 1995). These call "types" differ in that aggressive calls have a relatively greater number of pulses per call, longer call duration and a lower dominant frequency, though these call types grade into one another along a spectrum of these parameters. Advertisement calls are more attractive to

females, while aggressive calls signal aggressive motivation to rival males but are discriminated against by females. Males often call at intermediate levels, and Grafe (1995) suggested that this graded signalling system may allow males to interact aggressively with rivals while maintaining a degree of attractiveness to females. Graded signals as a solution to this aggression/attraction trade-off have been suggested in several anuran species (discussed by Owen and Gordon 2005).

Though gradedness in signals allows increased flexibility, this added flexibility has been suggested to increase the potential for ambiguity in a signal's meaning (Morris 1957). This is thought to be especially true for species living in habitats in which signals may be easily degraded by the environment, such as a dense forests in which aspects of visual and auditory signals can be distorted or obscured by surrounding trees (Marler 1975). As such, it has been proposed that such species should favour discrete signals. Conversely, species living in open habitats without such impediments to signalling may be able to alleviate any potential ambiguity due to gradedness by producing signals composed of multiple redundant components or multimodal signals, allowing the benefits of gradedness without ambiguity costs (Marler 1976; Johnstone 1996). Similar arguments regarding signal degradation and a flexibility/ambiguity trade-off should apply to the typical distances across which signals need to be transmitted, meaning social structure may play a role here too (Owings and Morton 1998). Ambiguity will be most detrimental when inappropriate responses by receivers have the highest fitness consequences for signallers and receivers. This is likely the reason that predator warning calls of many species are discrete (Blumstein 1999), particularly when animals are preyed upon by multiple predator types, each requiring different escape strategies (Seyfarth and Cheney 1990).

## How Are Discrete and Graded Signals Studied and What Has Been Revealed?

Researchers often endeavour to describe a species' signal repertoire by counting the

number of discrete signal types produced by that species, with larger repertoires considered more cognitively demanding to correctly produce and perceive (Freeberg et al. 2012). However, whether signals in a repertoire are genuinely discrete or graded can be difficult to parse. Originally, categorizations of signals as discrete or graded were purely a judgement call, as were the divisions between apparently different categories of discrete signals. These judgements were based on the experience of human observers observing through human sensory systems, which often differ drastically from those of the species under study, raising the possibility of erroneous categorizations (Von Uexküll 1909). As instruments for recording, measuring and analyzing signals have become more sophisticated, researchers have been able to employ less-biased quantitative approaches to categorizing signals and repertoires. This has been especially true for acoustic signals, as current software allows signals to be decomposed and compared along several dimensions with high precision (e.g., Wadewitz et al. 2015). This allows precise descriptions of call types and analysis of whether call types grade into one another through a series of intermediates. Obtaining precise quantitative descriptions of signals in other modalities, such as facial displays in the visual modality (Preuschoft and van Hooff 1995), currently represents a greater challenge, but advances in image analysis and machine learning techniques may enable similar advances in the future (Winters et al. 2020). When these quantitative techniques have been applied to signals, they often present a more complex and ambiguous picture than the neat distinctions between graded and discrete signals often applied by human observers (Keenan et al. 2013; Wadewitz et al. 2015), but they have also lent some support to such human categorizations (Tallet et al. 2013).

Quantitatively understanding signal structure is essential when understanding the selective forces that have shaped signals (Endler 1992). However, the presence of variation in signal parameters is only evolutionarily meaningful if receivers can perceive this variation and use that information to make decisions (Marler 1977).

Species' sensory systems will determine the granularity with which they can perceive differences in signal magnitudes of graded signals (e.g., just noticeable differences; Wysecki and Stiles 1982), meaning that not all signal variation may be perceived. Additionally, responses of receivers of a species to signal variation may deviate importantly from a simple positive linear relationship between signal magnitude and strength of response (e.g., complex preference functions; Edward 2015). As such, though gradedness of signals emitted by signallers is a prerequisite for a graded signalling system, graded perception and response by receivers must be assessed. This can be approached by investigating neurological responses to signal perception (e.g., Toscano et al. 2010), but in animals, receiver perception is primarily investigated via playback experiments (McGregor 1992). Playback experiments using acoustic stimuli have predominated due to their relative simplicity when compared to other modalities, and these have revealed graded responses in many systems (Burmeister et al. 1999; Wilson and Evans 2012; Goutte et al. 2010). More recently, innovative use of robotic models and video stimuli has also allowed graded signals and receiver responses to be demonstrated for visual signals (Ligon and McGraw 2018; Ord et al. 2002; Patricelli et al. 2006). However, as with quantitative signal analysis, playback experiments often present a complex and sometimes ambiguous picture regarding receiver perceptions and responses as graded or discrete (Fischer 1998; Fischer et al. 2001).

Empirical investigations of signalling systems, such as those mentioned above, have prompted a growing realization that signals are almost always extremely complex and are often composed of multiple components from across multiple signal modalities (Hebets and Papaj 2005). Signals seldom convey information along only a single isolated axis, and in many signals, graded and discrete elements are used in conjunction to expand the range and specificity of information transmitted. For example, meerkats have discrete calls for different predator types, but the acoustic

properties of these calls vary in a graded way which indicates the level of arousal of the signaller and the severity of the current threat (Manser et al. 2001). Thus, classifying entire signalling repertoires as graded or discrete is probably overly simplistic (Keenan et al. 2013). However, through careful application of these concepts to specific signals or separate components of multicomponent signals, these categorizations can shed light on the selective forces favouring discrete or graded signal elements and repertoires.

### Definition

The grandmother hypothesis is a theory explaining why longer post-reproductive life span has developed in human evolution and why infertility in old age can be an evolutionary benefit for females.

### Introduction

While our ancestors – comparably to today's apes – could become 40–50 years old, modern humans may double this life span. The aging process takes place equally quickly in all human organs – with an almost paradoxical exception: ironically, the reproductive organs of women age much faster. Menopause marks the end of the fertile life span and is a universal feature of human females; up to a third of the average female's lifetime is postmenopause (Harman and Talbert 1985). This is undoubtedly in need of explanation because according to Darwinian

theory, one should expect that a shorter reproductive span would impair fitness and therefore would not be expected to provide any evolutionary benefits (Hamilton 1966). This raises the intriguing question of why evolution prolonged life altogether, but not the fertile lifetime? Why did evolution produce sterile grandmothers instead, a phenomenon extremely unusual in the rest of the animal kingdom? The grandmother hypothesis provides an adaptationist explanation for this evolutionary conundrum and builds on the previously postulated “mother hypothesis.”

According to the “mother hypothesis,” it may be more advantageous for females to renounce further reproduction at some point and to put the resources into the well-being of the already born children due to the increasing risks of late-life pregnancy (Williams 1957). This “mother hypothesis” was extended to the “grandmother hypothesis” which proposes that post-reproductive females increase their inclusive fitness by investing in their daughters' fertility and their grandchildren's survival (Hawkes et al. 1997).

Presumably, the prolonged post-reproductive life span might have evolved as a consequence of the food sharing practice in humans' ancestors and is suggested to have emerged with climate-driven changes in the late Plio-Pleistocene. These ecological changes and the prolonged juvenile dependency due to increased cranial capacities may have forced hominins to change their foraging practices and to opt for more challenging but valuable foods such as tubers that required adult skills to harvest and process. These dietary demands may have constrained female birth intervals and fertility. Thus, provisioning grandmothers who increase the foraging productivity would increase their daughters' fitness benefits, whether by increasing the number of offspring or ensuring the survival of existing offspring (Hawkes 2004).

### Evidence for

Demographic studies in humans support the grandmother hypothesis and show that the presence of menopausal females is associated with an

increase in their daughter's reproductive success and grandchildren's survival (Lahdenperä et al. 2004; Sear and Mace 2008). The most compelling evidence come from the research on Hadza, a hunter-gatherer society living in the Tanzanian savannah (Hawkes et al. 1997). There, older women contribute extra food, which increases the fertility of their adult daughters. In this ethnic group, women and children are active collectors. However, since infants are still inept when dealing with large roots, i.e., the main food component, the mother's success in foraging has a measurable effect on the nutritional status of her children. Nursing mothers, however, can spend less time looking for food, so the task of the postmenopausal grandmothers is to provide food for the newly weaned children. These environmental conditions to which Hadza is exposed emphasize the particularly important opportunity for older women to increase their fitness despite the decline in fertility, namely, if they help the newly weaned grandchildren, mothers can have shorter interval births without compromising their children's chances of survival.

### Alternative Explanations

As intuitive as the "grandmother hypothesis" is, that postmenopausal survival does not have to be a biological adaptation. It could also be that post-generative longevity is to be understood as a nonfunctional by-product of a selection for increased pre-menopausal vitality (Peccei 2001b). A spacecraft set up to reach a distant planet will continue to shoot out in space once it has served its original purpose. To install a self-destruct mechanism would be more expensive than leaving the spacecraft to its fate. Thus, post-menopausal survival would be a surplus, as a fly-by phenomenon, and a by-product of a selection that favored pre-menopausal survival (Peccei 2001b). However, such a nonfunctional interpretation in no way excludes the possibility that the years of life gained are secondarily seized by adaptive behavioral strategies, such as typical grandmother behavior. It is only doubted that the adaptive possibilities created by an increase in life span formed the motor of evolutionary

life extension. The average human longevity would, therefore, be an originally functionless evolutionary by-product, which would have gained secondarily evolutionary significance with the "invention" of the grandmother role.

### Maternal Versus Paternal Grandmothers

Interestingly, evidence suggests that maternal and paternal grandmothers' effects may be different. For instance, Volland and Beise (2001) pointed out that the helping grandmother, who helps her daughters and their children, is less likely to care for her sons and their children. Many studies report that the paternal grandmother's family support is either less pronounced, not measurable, or even negative (see Fox et al. 2010 for a review). Mother-in-law has taken on the role that the vernacular implies. One explanation for this could be the fact of latent paternity insecurity. While women can be sure of their genetic relationship with their children, there is no comparable safety for men. Maternity is directly perceptible, but paternity is assigned. The assigned paternity may or may not be genetically identical, leading to the evolutionary consequence that the probability of shared genes between grandparents and their grandchildren in the male line is always lower than in the female. The mother-in-law's interest in her daughters-in-law only goes as far as her daughters-in-law work toward the reproductive interests of the mother-in-law. The different interests of the daughter-in-law, however, find no support. From all this it follows that the grandmother's evolution cannot be thought of without the mother-in-law's evolution: there are two social strategies, namely, "helping" and "social manipulation," which could have favored the evolution of the post-generative life span.

### Toothed Whales' Grannies

As mentioned above, long female post-reproductive life spans are rare in the animal kingdom and, apart from humans, have only been confirmed to exist outside of captivity in

the short-finned pilot whales, *Globicephala macrorhynchus*; the killer whales, *Orcinus orca*; the belugas, *Delphinapterus leucas*; and the narwhales, *Monodon monoceros* (Croft et al. 2015; Ellis et al. 2018). Killer whales represent a suitable model organism for studying the potential benefits of long-lived grandmothers. Similar to humans, they are extremely long-lived compared to other highly developed mammals and have a sex-specific mortality rate, with males reaching 50 years or less, females living almost twice as long, and females having one of the most extended post-reproductive life spans in the entire animal kingdom (Olesiuk et al. 1990).

First empirical data provide evidence that, in the killer whales, the oldest females of the group pass on their experience to the next generations. For example, they can “report” on historically good hunting grounds or contribute to the dissemination of group-specific dialects (Brent et al. 2015), in other words, pass on cultural information or help with additional care. Foster et al. (2012) provided evidence that calves, at least at a certain age, benefit from the help of their grandmothers and the reproductive life span and interbirth interval of the daughters also seem to be related to grandmotherly presence. Therefore, the menopause and long post-reproductive life are by no means a peculiarity of the genus *Homo*.

## Critique of the Grandmother Hypothesis

While the grandmother hypothesis won a large following, it remains a highly controversial topic in evolutionary anthropology since the evidence from contemporary hunter-gather societies and historical data produced mixed results. Some critics have cast doubt on the hypothesis because of several reasons (for a review see Peccei 2001a). One of the fundamental flaws, however, is that it fails to explain longevity with continued spermatogenesis in males and completely ignores the contributions of other family members to offspring survival.

## Conclusions

Although there is substantial evidence that grandmothers provide significant survival and reproductive benefits to their grandchildren, the evolutionary status of menopause and prolonged post-reproductive life span is still unclear (Croft et al. 2015). Is it a biological fit to enhance the reproductive fitness or rather a nonfunctional “burden” from the mammalian tribe’s history? Is postmenopausal survival a sort of “by-product” of pre-menopausal vitality selection, or is it the care of the post-reproductive women that have driven the evolution of human longevity? Future research that looks at the grandmother effects more broadly, including grandfathers, grandmothers, fathers, uncles, aunts, and siblings, will give new insight into the evolutionary pressures that are likely to have shaped human life history evolution. Finally, the fact that long post-reproductive life has also been found in non-human mammals highlights the importance of widening the taxonomic test bed for the evolutionary theories of menopause and provides intriguing opportunities for future research.

## Synonyms

[Clutching](#); [Grasp reflex](#); [Gripping](#); [Holding on](#)

## Introduction

The grasping reflex is a group of several primitive reflexes found in healthy newborns. Like all reflexes, they are an involuntary and unalterable motor response provoked by a stimulus. These reflexes may vary from one species to another depending on life’s conditions but are always inherited (Pedroso 2008).

## The Different Groups of Grasping Reflexes

Grasping has been studied under several names throughout time. As well mentioned by Schott and Rossor (2003), Seyffarth and Denny-Brown (1948) were able to separate these into two distinct groups: the grasp reflex and the instinctive grasp reaction:

**The grasp reflex** is composed of two phases. First, children’s fingers close when the examiner

## Grasp Reflex

- [Grasping Reflex](#)

stimulates the palm of the hand, usually by introducing a finger between the thumb and the forefinger (Berg 2014). This is called the “catching” phase. After that, if light tractions are made on the tendons of the flexor or adductor muscles, it will develop into a second phase called the “holding” phase (Futagi et al. 2012; Schott and Rossor 2003; Seyffarth and Denny-Brown 1948). The thumb may also be involved in gripping depending on the size of the object (Schott and Rossor 2003).

**The instinctive grasp reaction** is a small chain reaction performed when a stimulus is placed on any part of the palm of the hand. These movements are aimed at bringing the stimulus closer to the center of the hand in order to trigger a grasping phase. Nevertheless, it is a different catching phase from the first one in that it is induced only by a stationary presence of the stimulus (Schott and Rossor 2003; Seyffarth and Denny-Brown 1948).

The grasp reflex is already present and observable in utero. In the definition given by Berg (2014), the reflex appears from 28 weeks of gestation to become strong at 38 weeks; however, Sherer (1993) was able to observe it from 16 weeks of gestation from an ultrasound that showed the fetus retaining the umbilical cord. This reflex disappears in the first months of life and gives way to a voluntary grasp of objects by the child (Berg 2014).

The foot also has a grasp reflex when the sole of the foot is properly stimulated. Usually called plantar grasp reflex, this reflex is induced when the examiner performs pressure behind the toes, which causes flexion and adduction of the toes (Futagi et al. 2012; Schott and Rossor 2003).

## The Grasping Reflex in the Field of Medicine

These grasp reflexes should disappear during the first months of the child’s life. However, they may reappear in pathological states usually in case of lesions of the frontal lobes, which show that, although they are suppressed during the normal development of the child, reflexes are not lost (Schott and Rossor 2003). Testing the

presence of these reflexes during the maturation of the child makes it possible to determine its neurodevelopment. A primitive reflex is considered abnormal if it is absent, diminished, or exaggerated during the normal reflex period or if it does not disappear after this period of time (Futagi et al. 2012).

## The Grasping Reflex in Other Primates

The grasp reflexes are also present in newborn monkeys and apes. As well mentioned by Futagi et al. (2012), this suggests that, even if these reflexes no longer have any purpose for human species, they are rudiments of phylogenetic functions needed for juvenile monkeys in their arboreal life for support and locomotion. Indeed, the studies that Futagi et al. mention suggest these reflexes are even stronger in nonhuman primates. Richter (1931) conducted a study on five monkeys from a rhesus macaque colony and succeeded by demonstrating that the newborn macaque grasp reflex was much stronger than the reflex of the newborn human. One of the monkeys had managed to remain hooked for 33 min to a rod with one hand. According to Richter, the subject would have been able to hang for hours if it had used both of its hands. A similar study carried out by Robinson (1891) on humans demonstrated that the newborn was able to withstand his own weight hanging from a horizontal rod. The record obtained during this study is, however, only of 2 min and 35 s using two hands. Brain and Curran (1932) also support the idea that monkeys have true reflex grasping because, from their earliest days, they are able to cling to the mother’s underside with their hands and feet without any support.

## Conclusion

In conclusion, the grasping reflex is a group of several reflexes, very probably homologous across the primates, all of which lead to the grasping. They are an involuntary response to a stimulus. In the field of medicine, their presence and

their disappearance make it possible to monitor the development of the child and to establish the presence of brain damage in adults.

## Green Beard

Renu Bala and Kiran Singh  
Department of Molecular and Human Genetics,  
Banaras Hindu University, Varanasi, India

## Definition

Green beards are genes that can identify the presence of copies of themselves in other individuals and cause their bearer to behave nepotistically toward those individuals (Gardner and West 2010).

## Green Beard: an Evolutionary Strategy of Cooperation

According to evolutionary biologists, evolution is an entity which functions to ensure the survival of the best fitted individual. However, sometimes nature selects the traits which are not the best survivors but unique (Haig 1996). These unique traits are selected not for the individual carrying the trait but for the benefits of the reproductive family members within the colony such as sterile workers in the insect colonies (West et al. 2010). Then the question arises that why would natural

selection choose a trait that does not benefit the immediate bearer of the trait? This could be explained with the idea that the presence of such unique traits in an individual indirectly benefits its future generations/lineages. Carrier of these unique traits would put themselves on stake for the benefits of their closely related family members (Darwin 1859). Such interactions have been previously explained with the altruism where indirect benefit is more than the personal cost (Hamilton 1964).

All these social interactions come under the category of cooperation which is an intricate evolutionary phenomenon of mutual benefits. But somehow this phenomenon is highly susceptible to exploitation when cooperative groups get invaded by cheaters, ones who get the benefits but do not reciprocate. In these conditions, cooperative systems tend to collapse (Laird 2011). In such systems, green beards function as rescuers and introduce a convenient way for cooperation to evolve and ensure that cheaters do not get any benefit from cooperative groups. The idea of green beard allele was proposed by William D. Hamilton (1964), and this term was coined by Richard Dawkins in his book *The Selfish Gene* (Dawkins 1976). Green beard is a certain gene with a particular phenotypic marker discriminately favoring the individuals with that phenotype only even if they do not share any other genes. In this case, the selected genes might or might not have an observable distinguishable phenotype but encode a characteristic behavior which ensures the discriminative selection toward the carriers of that gene. Green beards show high degree of relatedness at the green beard locus and other closely linked gene loci. Main functions of green beard gene/locus are to establish a signal, discriminative exclusion of noncooperators, and cooperative behavior favoring other green beards (Queller et al. 2003); if all of these characters are controlled by two different genes or distantly related loci, then there are more chances of them being uncoupled during evolutionary mechanisms which renders the green beard effect useless.

High degree of self-recognition at genetic locus preferentially distributes the green beard

gene/locus within green beard groups. But the probability of the presence of other genomic parts in such groups of donors and recipients (including green beard siblings) depends on its closeness to green beard locus. Also there are genetic modifiers of green beard locus whose selection will depend on their closeness to the green beard and whether they facilitate the selection of green beard locus or not. Modifiers linked in coupling and favoring the locus (enhancers) will be under high selective pressure than the ones disfavoring it (suppressors) or present on different chromosomes (Haig 1996).

Green beards are different from genetic kin recognition as green beards are social interactions that are related to the direct perception of genetic identity at a particular or closely linked locus (Dawkins 1976), while genetic kin recognition is based on the phenotypic similarity due to genealogical relationship over the whole genome (Hamilton 1964). Earlier green beards were thought to be highly unlikely in nature, but new investigations have shown that green beards are not as unusual as it was considered to be. In slime mold, *Dictyostelium discoideum*, cells containing *csa* gene, cooperatively adhere to each other to form the aggregated stalk to become fruiting bodies while excluding noncarriers of the gene (Ross 1997). In another remarkable example, green beards are observed in red fire ant (*Solenopsis invicta*) polygyny (multiple-queen) colonies where the queens with Bb heterozygous genotype (where b allele produces specific odor to determine if the prospective queen carries the b allele or not) at Gp-9 gene locus reproduce successfully, while queens with bb genotype die prematurely due to internal causes (Fletcher and Blum 1983). Queens with BB genotype are killed by the aggressive workers with Bb genotype. Identification and execution of BB queens may be due to the two signaling cues that represented queen's reproductive state and her Gp-9 locus genotype. Pheromones produced by sexually mature queen can be assessed by the workers (White and Winans 2007). Gp-9 locus linked to green beard gene can produce a chemical signal which can induce the workers to kill all sexually mature females except those carrying the same chemical

signal (Bb queens) encoded by this allele (Keller and Ross 1998).

Green beards have been distinguished into four kinds depending upon their characteristic evolutionary behaviors such as “helping” ( $rB > 0$ , Hamilton’s rule, where  $r$  is the coefficient of genetic relatedness between actor and recipient and  $B$  is benefit to recipient), “harming,” “facultative” (facultative harming, e.g., Gp-9 gene of the fire ant (*Solenopsis invicta*); facultative helping,  $b/c > 1$  (where  $b$  is benefit to recipient and  $c$  is the fitness cost to actor and if the benefit to the recipient outweighs the cost to the actor), e.g., cell surface gene FLO1 in the yeast *Saccharomyces cerevisiae* where cells adhere with other cells containing the FLO1 gene (Smukalla et al. 2008) and in slime mold *Dictyostelium discoideum* (Ross 1997) and  $b$  allele at the OBY locus in side-blotched lizards where  $bb$  males with blue coloration throat function as a mate guard of genetically similar but unrelated and protect them against yellow aggressive males (Sinervo et al. 2006)), and “obligate” (obligate helping,  $b/c > 1/p$ , i.e., where the ratio of benefit to cost exceeds the reciprocal of the green beard’s frequency in the population ( $p$ ), e.g., the tumor-inducing (Ti) plasmid in the bacterial plant pathogen *Agrobacterium tumefaciens*; obligate harming, e.g., bacteriocin-encoding genes, which are present in all main bacterial lineages and provide antimicrobial activity). Immunity from toxin is provided by clone mates of producer cells which show the tight linkage between bacteriocin-encoding gene and the gene which deactivates the bacteriocin (Sinervo et al. 2006).

Sometimes the gene gets selected in the course of evolution even if it is disadvantageous to its bearer but has sufficiently large benefits to the relatives because the relatives also carry the replicas of that gene. But this concept cannot be generalized as the probability of carrying each gene similar to your relative is questionable given into account the environment, mutations, and other genetic forces that play a role during development of an individual (Hamilton 1964). And this applies to all four different kinds of green beards. When a rare green beard will be favored, it will undergo

frequency-dependent selection which will ultimately lead to its fixation. Consecutively most of the population will display green beard, individuals will be treated equally, and it will eliminate its function as a characteristic phenotypic/behavioral marker among cooperative individuals. This would make the green beards resistant to identification in such populations. Also the requirement of single-gene/locus system in green beards increases the chance of false beards with cheating genotypes. Thus multi-allelic system of green beards was postulated in social amoeba (*Dictyostelium discoideum*) at Tgr gene locus explaining the specificity required by individuals to direct cooperative behavior toward matching partners and reduce the fitness cost caused by chimeric shifts (Gruenheit et al. 2017). Adding more loci would also prevent against disruption of linkages due to intragenomic conflict and intrusions by false beards (Haig 1996). However, this might be the reason behind numerous examples of green beards in microorganisms where relatively simpler genotype and phenotype correlation prevents the decoupling of beard and behavior. We do not find much examples of green beards in other hierarchal systems as we often look for simple ones with few genes and categorize the complex shared gene interaction as kin selection (Sinervo et al. 2006). But green beard organisms present a remarkable evolutionary picture of social interactions for the survival of species where individuals interact/cooperate with each other either for mutual or indirect fitness/benefits.

## Introduction

The dawn of the twentieth century witnessed an important discovery that had been biting the dust for more than three decades, and it took three independent researchers – Hugo de Vries, Carl Correns, and Erich von Tschermak – to rediscover the results from the 8-year long study of G. J. Mendel (Fig. 1), which answered the questions related to fundamentals of life. Although this came as a shock to the scientific community that a study with this kind of impact went unnoticed for such a long time, it would be a huge lie to render that Mendel’s results were

**Gregor Mendel, Fig. 1** Gregor Johann Mendel. (Pic Courtesy: MaterialsScientist, Wikimedia commons)

totally in the dark after getting published, as there had been multiple citations of his published article between years 1868 and 1900 (Brannigan 1979). After one and a half century of publishing, Mendel's results have brought us to interact at gene level, and to honor him, we refer to him as the "father of modern genetics."

The knowledge of an achiever's past and upbringing helps the subsequent generations to understand the environment and the factors that had been stitched together to have led to the achievement. Right after the rediscovery of Mendel's results, biographers have travelled up and below to know every bit about him, his family, his upbringing, and all about his history. But as the rediscovery took 34 long years which includes 16 years of Mendel's demise, it was difficult to explore the facts about his upbringing and history. Had it not been his nephew, Alois Schindler (1859–1930), the son of Mendel's sister Theresia, we would have not known Mendel's pedigree (Klein and Klein 2013). In this entry, we will learn concisely about the past of Gregor Johann Mendel from the efforts of multiple biographers.

### **Mendel's Infancy and Uncertainty About His Date of Birth, Name, Family, and Village**

Mendel was born to the peasant couple named Anton Mendel and Rosina (Schwirtlich) Mendel in Heinzendorf. The year of his birth was 1822, but there surrounds a confusion regarding the date. Two dates are to be considered: July 20 and July 22, 1822. The former is the date recorded in the parish (baptismal) register and indicated on Mendel's birth certificate; the latter is the date transmitted to us through family tradition. If the register which records baptism on the same day of birth is to be followed, then a controversial situation of a child being baptized (according to the register) before being born (according to the family tradition) arises. According to the Mendel family tradition, Johann Mendel was born on Saint Magdalene's Day, which comes on July 22 (Klein and Klein

2013). This was also confirmed by Alois Schindler who recorded that his mother Theresia, Johann's younger sister, as well as other relatives, insisted that in the family Johann's birthday was always celebrated on Saint Magdalene's Day.

The name also carries quite a bit of history along with it, while the surname was that from the father's side, the middle name also has a connection to his father's family as he was baptized Johann after his uncle, Anton Mendel's younger brother contrary to the belief that Mendel got his middle name from Saint John as he was born few days before Saint John's day. He assumed his first name Gregarious (Gregor in German, Rehor in Czech, and Gregorios in Greek, meaning "vigilant") at a robing ceremony, where he received the habit of a St. Augustine friar on October 9, 1843. It was after this ceremony he started signing as Gregor Johann Mendel (Klein and Klein 2013).

In the family apart from himself and his parents, Mendel had four sisters. The older was Veronika and three younger were Rosina, Theresia, and Rosina, in sequence of their birth order. Both Rosina died shortly after their birth, the reason to which is not known. Biographers considered Theresia to be more close to Johann than Veronika because of the fact that Theresia renounced her right on a dowry to enable Johann the continuation of his studies and later he enabled Theresia's sons to study and that it was through them that most of the information about the Mendel family has reached us (Henig 2000).

The village of Hyncice (Fig. 2) from the Odra domain was Mendel's birthplace, the German name of Hyncice is Heinzendorf. This village lies near the Moravian–Silesian border in what is now the Czech Republic (at that time part of the Austrian empire) (De Castro 2016).

### **The Childhood and Nurturing of a Naturalist**

Later in this entry, we will learn that the decision to become a priest and not return to his farm didn't had any inspiration from his upbringing as

**Gregor Mendel, Fig. 2** Mendel's home at Hynčice. (Pic Courtesy: Vit Lang)

there is no reporting that Mendel's family was religiously too forward or was there any predetermination in him to become a monk. The biographers believe that Mendel was just a normal village boy in his childhood who in his free time climbed the trees to fetch twigs, gazed the sky for birds, raided the nests, and knew where to fetch for the edible mushrooms or find the berries which were large, sweet, and juicy. All the while, being in continuous exposure of the nature would have given him the unconscious expertise to develop as a naturalist. Along with these expertise, he would have had some added advantage over other children of his surrounding which would have induced a lifelong attachment to the nature. This added advantage would have attracted his teachers, Thomas Makitta and Johann Schreiber, who must have started to nurture the talent (Bateson 1909).

Johann Schreiber was a priest and an experienced horticulturist who resorted to asexual propagation of plants by grafting as he knew that the hybrids, if propagated sexually, will produce different types of offspring and the original type may all but disappear. He usually taught religion to children, but more than anything else, he liked to spend the time with them in the garden, showing them how to prepare the scions and the stocks for grafting. Being a priest with

vast knowledge about fruit plants enabled him to become one of the founding members of the Pomological Association in Brno in 1816. On the other hand, very little is known about Thomas Makitta. He was a farmer's son, born in 1774, and later became a certified teacher. He started at the Heinzendorf elementary school either in 1795 or 1796 and taught religion as well as principles of horticulture and beekeeping, presumably until 1850 (Schwarzbach et al. 2014).

Since both his teachers were fond of trees, plants, and animals, the child's interests were too directed on the same path, leading to questions. The increment in child's interest must have pleased his instructors, and so they would have paid even more attention to him. In the end, this mutual psychological amplification of the bond between the child and his teachers led to the fixation of his interests, thus laying the foundation for the development of a future naturalist (Dunn 2003).

### **Stretch to Lipnik Followed by a Jump to Opava (or Troppau)**

Having experienced the talent of Mendel's intelligence and his eagerness to learn, Schreiber and Makitta must have thought that he should

be given the opportunity to receive a higher education. But before that, they wanted him to move to a school in Lipnik, a town 20 km from Heinzendorf, to complete the sixth year of his compulsory education. To move the boy away from his home and family, the teachers had to convince his parents. The convincing part is supposed to be done by Makitta, as recorded by Alois Schindler, and seems to make sense as he was Mendel's main teacher (Klein and Klein 2013). But, there are other arguments in Schreiber's support because being a spiritual leader of the community he was better acquainted with the individual families and also he must have had contacts in Lipnik school. To add to this in his letters to home, Mendel added frequently greetings to the priest, but never to Makitta which has been interpreted as a sign of Gregor's gratitude to the former for his help in convincing the parents. Finally, after the consent from both the parents, the 11-year-old Mendel packed his meagre belongings and said goodbye to his family, home, and childhood and moved to Lipnik in fall of 1833 (Dunn 2003).

The year passed, and in the summer of 1834, the 12-year-old Mendel became the Pramianten, i.e., the prize-winner. Considering the odds against him, this achievement was remarkable for a boy who had to adapt to being alone, away from home, and to an entirely new way of life and a new environment. Apart from everything else, this would have contributed to his father's decision to allow Johann to continue his studies in the Gymnasium in Opava (or Troppau). After Mendel's father gave his definitive decision, Makitta and Schreiber would have prepared for him the application for his admission to the Opava Gymnasium. It was also at that time that Schreiber sent to the Gymnasium the birth certificate with the wrong birth date. The teachers recommended the Opava Gymnasium because it was the closest to Hyncice or Heinzendorf and because of its good reputation. Johann was accepted and reported to school on December 15, 1834 (Klein and Klein 2013).

Opava was the capital of Czech Silesia and was the center for numerous institutions, courts, and governmental offices and had a chamber of commerce with several banks, custom offices, a

number of clerical institutions, churches, monasteries, a military battalion, a theater, a museum, hospitals, an array of schools for general and specialized education, and a rapidly growing textile, machine, and other industries. A city with a recorded history since 1224, it amounted for a lot of adjustment on the part of Mendel, a small-town boy. The Baroque building in Opava is the place where Mendel went to school from 1834 to 1840, and this is being displayed on a commemorative plaque at its entrance (De Castro 2016). Among all those years at Opava, the toughest was the year of 1838, as mentioned in his autobiography. Mendel's father met an accident leading to serious injuries to the extent that he became unable to attend to his farms from this point onward. Mendel came to know about the condition back at home on his return for the vacation, and it must have led to the thought that Mendel's wish of getting a full education might come to an end as he would now not be supported by his family and will have to look after the farm. But on the contrary Mendel's father became more resolute about the completion of his studies. To this encouraging belief from his father, Mendel moved toward self-sufficiency and got enrolled in a course for school candidates and private teachers at the Hauptschule in Opava, to obtain the permit necessary for tutoring other students. As one would expect from a bright student riding on the confidence entrusted by his father, Mendel not only cleared the course with highest marks, he was also able to find students on recommendation of the school for tutoring and thus was able to support himself through school. Mendel received Abgangszeugnis, a certificate attesting the successful completion of his studies in Opava and revealing him as a *Musterschuller*, a student whose example was given by teachers to students with lesser zeal toward studies. Along with the accolades for his diligence to studies, the city of Opava also gave Mendel the confidence of surviving on his own, and with these factors on his side, he decided to enroll at the Philosophical Institute in Olomouc, a city some 50 kilometers southwest of Heinzendorf (Klein and Klein 2013).

## Journey to Become “the Monk”

Mendel reached Olomouc in the year 1840 and spent 2.5 years. The Philosophical Institute looking into the circumstances of Mendel waived the tuition fee, but in order to pay for his rent and food, he had to earn from somewhere. In a city where the inhabitants spoke Czech and with no contacts to recommend him to parents looking for a tutor for their children, he somehow managed to keep his head above the water. The struggle continued till the end of first semester where he passed in mathematics and Latin but fell ill before completing the rest of them. He returned home where time was great as Veronika got married, and her husband, Alois Sturm, agreed to take over the Mendel farm, which Anton could no longer manage. Theresia was 11 years old and decided to forgo her part of dowry in favor of Mendel, a decision which allowed him to return to Olomouc in 1841 and complete his studies (Schwarzbach et al. 2014).

At the Philosophical Institute, religion, theoretical and practical philosophy, history, mathematics, and physics were among the obligatory courses, while pedagogy (the art and science of teaching), Austrian history, diplomacy and heraldry, numismatics, history of philosophy, classical literature, Greek philology, and agriculture were elective courses. Among the faculty, Prof. Dr. Friedrich Franz, who taught physics to Mendel, lived in the Augustinian Abbey at Brno and so came to know the friars or priests there quite well, including the Abbot Franz Cyrill Napp (Klein and Klein 2013). In 1843, Franz recommended Mendel as a suitable candidate for admission into the Augustinian (name of the religious order) order (De Castro 2016). The fact that almost all the professors Mendel knew were priests must have led to the thought that it was through priesthood that he will be able to get university level education and the post of professor; also he knew that after completion of his studies at the Philosophical Institute he could not expect of help from home and with his inability to support further studies all by himself he decided to become the priest or the monk. In his autobiography Mendel mentions that, “he found

himself forced to enter the profession and that his circumstances determined his choice to become a priest which would free him from worries about making a living” (Klein and Klein 2013).

Mendel got enrolled in the Theological Institute (officially known as *Caesario Regio ac Episcopali instituto theologico Brunensis*, translated as Imperial-Royal and Episcopal Theological Institute of Brno) in 1843. It trained candidates for priesthood and so was under the jurisdiction of the bishop. But he began his studies in September 1844. After completing 1 year as novitiate, his status at the abbey changed to juniorate; it was now that he became a candidate for priesthood. He took simple vows which did bound him to the monastery, but the bond was not quite unbreakable yet, and transgressions against the rule were pardonable (Henig 2000).

Due to the sickness, death, and incapacitation of many candidates at the abbey, there was a shortage of priests to perform the pastoral duties. This forced Napp to entrust one of the juniorate to the post of priest before completion of their studies in order to perform the pastoral duties, and obviously the choice was Mendel, who with his impressive accomplishments till date presented little risk of having the burden of pastoral work endanger the completion of his studies. However, there were two hurdles, first was Napp required the permission of the provincial government and the bishop, and second was Mendel’s age: the rules stipulated that a priest must be at least 25 years old, an age which Mendel would only reach after few months, i.e., on July 22, 1847. Napp countered the first hurdle on December 17, 1846, by asking the body of abbey’s chapter, to which they voted unanimously and asked Mendel to take the solemn vows. And so he did take the solemn vows on December 26, 1846, in a ceremony that took place in the parish Church of Virgin Mary, after preparing through a series of spiritual exercises. The second hurdle was something Napp knew couldn’t be waived. It was Napp’s good rapport with the civil authorities that helped him to obtain the approval to advance Mendel’s ordainment 1 year ahead of schedule. This struggle didn’t halt here, it

was understood that the Roman Catholic Church maintains a strict hierarchical organization where clerics have to pass through different levels of ranking order, namely, subdeacon, followed by the deacon, priest, bishop, archbishop, cardinal, and the pope, each with different sets of privileges and responsibilities. Hence, to become a priest, the order comprising of several years in between them must be followed, and a bishop should ordain a candidate ceremonially to each of these levels. However, in Mendel's scenario, the passage through the levels of subdeacon and deacon was accelerated subjected to the crisis of situation at the abbey. The bishop ordained him subdeacon on July 22, deacon on August 4, and priest on Sunday, August 6, 1847. Mendel then celebrated his first mass (the "Primiz") on August 15, 1847 (Klein and Klein 2013).

### Returning to School and String of Failure in Exams

In the year of 1848, Mendel was appointed as the full-time assistant of the parish priest, in other words he was the "man Friday" both in the church and the parish. The pressure of full-time pastoral work was immense as he had to do everything in between baptizing a newborn to burying the dead. He struggled to overcome the burden of work, but by the end of the year, he took to bed being seriously ill both mentally and physically through the entire beginning of the year 1849. Mendel's illness put Napp in a difficult situation of what to do of a priest who cannot withstand the pressure of pastoral work, especially if the ordainment of that priest was accelerated on his request. It must have been the fortunes of both Napp and Mendel that a request for an extra teacher came from the city Znojmo. Napp knew that Mendel had no teaching experience and no formal qualifications for the post (though he took the course for school candidates and private teachers at the district teachers' seminary at Opava and was highly recommended in the qualification report) but had no doubt that Mendel could handle the job. And so he recommended him for the position teacher, to which a message arrived inviting

Mendel to report immediately to Znojmo as a substitute teacher. Mendel assumed his teaching duties in Znojmo in the year 1849 and soon became popular among the students due to his vivid and lucid method of teaching, also his colleagues held him in high esteem (Schwarzbach et al. 2014).

In the same year, in order to tighten its grasp on the society and limit the autonomy of the institutes in educational field, the government directed that schools would no longer be allowed to employ substitute teachers who could not present a certificate that they were qualified to teach their particular subject. In order to obtain the required certificate, the eligible candidates had to pass a qualifying examination administered by Royal Imperial Scientific Examination Committee at the University of Vienna, established by the ministry. Mendel applied and failed in the viva portion in 1850. The very next year, he was sent to Vienna as suggested by the state examiners and Napp to continue his studies in science at the Royal Imperial University (Monaghan and Corcos 1993), the thought being that Mendel's failure seemed to be attributed to his lack of formal preparation. In Vienna, he studied physics with Christian Doppler (of Doppler effect fame) and botany with Franz Unger. Unger had been using a microscope for his studies and was meddling with a pre-Darwinian theory of evolution, both of which Mendel used particularly in mathematics to evaluate and analyze empirical data (Henig 2000). Mendel's time in Vienna was the high point of his education as up to that time he had been largely self-taught.

After 2 years of studies, Mendel went back to Brno in 1853 and was appointed as a substitute school teacher in natural history and physics. In the spring of 1856, Mendel was able to retain his position as substitute school teacher only by the virtue of being an excellent, enthusiastic educator. He failed the certification examination again even after having spent time at Vienna and having practiced as a full-time substitute teacher (Monaghan and Corcos 1993). It was from this year till 1863 that he diligently worked in his pea garden at St. Thomas Abbey in greenhouse foundation.

## Serendipity that Led to Beginning of Genetics

There has been a consensus among the biographers and researchers that by working on the peas Mendel did not set out to prove the laws of inheritance (Opitz and Bianchi 2015; Olby 1979), instead, he worked with peas to develop new color variants and to examine the effects of hybridization. Mendel paid special attention to plant breeding, a topic that fascinated him since his childhood back home, when he assisted his father or priest Schreiber as they grafted fruit trees and took care of them. At St. Thomas Abbey (Fig. 3), nurseries were established by Napp even before he became abbot. One of these nurseries was utilized by Mendel to study hybridization and develop new color variants of peas. His selection of peas was the serendipity, the reason to which is not known. Assumptions could be made for his selection as peas exist in pure, separate lines, they are hermaphrodites and able to self-fertilize before the bud opens, and great numbers can be bred in a small space (Reid and Ross 2011). Unknown to Mendel is the fact that the characters

he chose are not subject to linkage disequilibrium, and at least five out of the seven traits he used are on separate chromosomes (Blixt 1975) which made the analysis of crosses and any conclusions inferred from them straightforward. Mendel's pea experiments were carried out over 8 years and included more than 15,000 plants, and these are astounding numbers, even by today's standards. Mendel completed his work in 1863, prepared the manuscript after analysis of the data, and finally submitted his work on the laws of heredity, *Versuche uber Pflanzen-Hybriden* (*Experiments on Plant hybridization*), to the Proceedings of the Natural History Society of Brno in 1865, to be published in 1866 (Weiling 1991). His paper got few citations, but its importance was understood after more than three decades of publishing when in 1900 three botanists Erich Tschermak in Austria, Hugo de Vries in the Netherlands, and Carl Correns in Germany independently replicated his results only to find that the data and theory already had been published in 1866 by a monk named G. J. Mendel (Weinstein 1977). Mendel's article led to the foundation of inheritance theory, articulated later by Bateson and

**Gregor Mendel, Fig. 3** Panoramic View of St. Thomas Abbey. (Pic Courtesy: VitVit, Wikimedia commons)

Fisher (Fisher 1918; Bateson 1902). This also led to the birth of genetics in the early twentieth century.

### The Other Scientific Domains and His Final Years

Apart from his work on laws of heredity, Mendel also pursued other scientific domains. He was a well-trained mathematician and physicist and applied mathematical theories to interpret his biological experiments and to plan new ones (Opitz and Bianchi 2015). In 1865, he established the Austrian Meteorological Society and published numerous articles in meteorology, and he also did hybridization experiments on other plants (*Hieracium*), vegetable, and fruit tree horticulture (Walsh 1966), apiculture and agriculture in general (Weiling 1991). Mendel's data on the water table assessed from groundwater collection from a

nearby well are one of the most extensive physical and meteorological observations. Conserved in the Mendel museum in Brno are extensive records kept over the years of these data (De Castro 2016).

In 1868 Mendel was appointed as abbot of the monastery after Napp. The administration of the abbey took most of his time making him to abandon his illustrious pea experiment. In 1874, he introduced taxing of religious institutes which isolated him from his contemporaries due to public opposition. Many of his writings were destroyed in a fire to mark an end to disputes over taxation of religious institutions. Ultimately on January 6, 1884, at the age of 62, he took his last breath; the official cause of death noted in the autopsy report is Bright disease (nephritis), with heart and kidney failure (Dunn 2003).

The twentieth century was filled with discussion on the interpretation of Mendel's experiments. Few also questioned his protocols, motive, and beliefs about evolution and heredity

**Gregor Mendel,**  
**Fig. 4** Mendel's statue in  
monastery garden. (Pic  
Courtesy: Vit Lang)

(Singh 2015). His journey was filled with obstacles and disappointments, but as per the quotes of his last thoughts, “I have experienced many a bitter hour in my life. Nevertheless, I admit gratefully that the beautiful, good hours far outnumbered the others. My scientific work brought me such satisfaction, and I am convinced the entire World will recognize the results of these studies”. It took years before Mendel was given his rightful place in the field of science and very rightly was honored as “father of modern genetics” (Fig. 4).

## Synonyms

[Dog racing](#)

## Definition

An organized, competitive sport in which greyhounds are raced around a track.

**Greyhound racing** is a competitive, organized sport in which bets are placed as greyhounds run around a track (Baker 1996; Thompson 2003). There are two forms of dog racing, which include track racing and coursing. Track racing utilizes an artificial lure that travels along a rail ahead of the dogs until the hounds cross the finish line. In

contrast, coursing traditionally involves dogs chasing after a hare in a relatively open environment (Thompson 2003).

Modern **greyhound racing**, around a circular or oval track, has its origins with the invention of the artificial hare (Thompson 2003). **Greyhound racing** had its peak during the first half of the twentieth century and was particularly popular amongst a working-class audience, for whom evening races and tracks in urban centers were accessible (Ray 2001; Thompson 2003). Popularity for **greyhound racing** has waned in recent decades worldwide, and, at the time of writing of this entry, only five states in the United States still operate dog races (Baker 1996; Jackson 2001; Ray 2001; Sicard et al. 1999; Thompson 2003). Greyhound adoption programs have been wildly successful in helping to find homes for retired racing dogs, with an estimated adoption rate of over 95% in the United States.

Dog racing is dependent on the build and gait capabilities of the greyhound. Greyhounds are thought to be one of the oldest breeds of dogs, and were bred to hunt by outrunning their prey (Thompson 2003). As such, the greyhound has a number of anatomical features that allow the animal to generate remarkable speeds (Williams et al. 2008a, b). In general body form, the greyhound has long, powerful legs, a deep chest, highly flexible spine, and slim build. The greyhounds' heart is larger than similarly sized breeds and pumps blood with higher levels of red blood cells than other breeds. Since red blood cells carry oxygen, this higher level allows the hound to move larger quantities of oxygen faster from the lungs to the muscles (Herrmann 1926). The locomotor muscles of greyhounds consist of a large proportion of fast-twitch fibers compared to other similarly sized breeds, which tend to fatigue faster than other muscle types, but help to generate powerful bursts of movements like sprinting (Rodriguez-Barbudo et al. 1984).

Greyhounds are known to reach speeds of over 40 miles per hour. This remarkable capability can be attributed to its use of the rotary gallop, also referred to as a double-suspension gallop (Bertram and Gutmann 2009; Usherwood and Wilson 2005; Fig. 1). The double-suspension

gait is a four-time, asymmetrical gait, where the feet fall in a circular sequence around the body, and gets its name from the two aerial phases: a gathered aerial phase where the back is flexed and the hind feet pass in front of the forefeet and an extended aerial phase where the feet are stretched away from the body and the back is extended (Bertram and Gutmann 2009; Hudson et al. 2012). When running competitively, the greyhound is in the air 75% of the time. There are several theories as to why the rotary gallop may be beneficial for generating speed, including reducing momentum losses during stance (Bertram and Gutmann 2009) and allowing internal work to be stored in the elastic structures of the back, increasing efficiency (Alexander 1988). Despite the speed, the double-suspension gait doesn't offer much endurance (Hudson et al. 2012).

Despite similarity in size and build, the greyhound falls short of the remarkable running capabilities of the cheetah (*Acinonyx jubatus*) (Hudson et al. 2012). Three major limits have been proposed to explain an animal's maximum speed: peak limb force, minimum achievable swing time, and muscular power (Hudson et al. 2012; Kram and Taylor 1990; Usherwood and Wilson 2005). Hudson et al. (2012) observed several differences that may account for the cheetah's ability to generate faster speeds than the greyhound. The cheetah's longer limbs and back allow it to attain longer stride lengths. This, coupled with the cheetah's ability to reduce its swing times, contribute to it achieving faster maximal speeds than the greyhound. The range of swing times used by both species indicates that the minimum possible swing time was not often utilized and cheetahs in particular may attain even higher stride frequencies at greater speeds by reducing swing time. In both species, Hudson et al. (2012) observed that the forelimbs maintain a constant peak force with increasing speed, reducing vertical impulse as stance time decreases. Despite this, it seems unlikely that a peak force limit has been reached as other locomotor tasks (e.g., turning, prey capture) are likely to require the forelimbs to resist higher peak limb forces than those during straight line steady-state galloping. The hind limbs

**Greyhound Racing, Fig. 1** Gait characteristics of greyhound running. The greyhound is capable of achieving remarkable speed due to the double-suspension gallop (a), aka the rotary gallop, which is characterized by two

aerial phases: an extended aerial phase where the feet are stretched away from the body and the back is extended (b) and a gathered aerial phase where the back is flexed and the hind feet pass in front of the forefeet (c)

contributed a greater proportion of body weight support at higher speeds.

## Definition

Grooming behavior is a physical process that functions to maintain the form and composition of an animal's body surface.

Grooming behavior is seen across a diverse range of animal taxa, including, for example, arthropods, birds, canids, felids, mongooses,

primates, rodents, and ungulates. Grooming is a physical process that serves the primary function of maintaining the form and composition of an animal's integument (i.e., skin, hair, feathers, or scales). Self-grooming, or auto-grooming, is the term used to describe an individual grooming its own body, and allogrooming is the term used to describe one individual grooming the body of another.

Taxa-specific differences exist in the behavioral form of grooming and the functional value it holds to those participants involved. Whereas arthropods typically groom by rubbing their own body parts with their legs or between their mouthparts, birds use their beaks to groom (otherwise known as preening), and feet to scratch, their plumage. Most mammals use either their tongues to lick, or lower incisors and canines as a dental comb to scrape, when grooming their pelage. Grooming among primates is typically a bimanual process, whereby the groomer sweeps through the pelt with their hands. Monkeys and apes are particularly skilled groomers, a consequence of the enhanced dexterity afforded by their highly opposable thumbs (“► [Precision grip](#)”). The strepsirhines (i.e., lemurs and lorises), who lack such a precise grip, more commonly rely on the use of a dental comb to scrape when grooming.

Almost all animals devote a significant amount of time to self-grooming, providing a range of taxa-specific benefits (e.g., thermal, anti-infective, hygiene, communication) that can improve individual “► [Fitness](#).” Maintaining the integument in and of itself plays an important role in “► [Thermoregulation](#).” For hair-covered mammals, grooming can prevent the hair from matting and helps distribute sebum along the hair shaft. Such maintenance facilitates piloerection and the overall thermal efficiency of the pelt, which helps animals compensate for changes in their environment without experiencing the water-loss and increased energy expenditure associated with autonomic thermoregulatory processes. In addition to its comparable role in thermoregulation, a bird's plumage plays an important role in flight, and thus maintaining its form via preening also serves an important locomotory function. Ritualized displays of preening are thought to play

a communicative role in courtship displays (“► [Courtship Rituals](#)”) among birds.

Some animals use grooming as a means to distribute secreted chemicals over their body’s surface, providing various protective functions. Where possible, most mammals will use their tongues to lick a wound to receive the antibacterial benefits of saliva that promote wound healing. Anogenital licking, observed most commonly among rodents, can facilitate sexual development and reduce the spread of certain diseases and sexually transmitted infections.

Some birds supplement preening behavior with anting, a self-anointing behavior (“► [Anointing](#)”) during which the birds rub ants on their skin and feathers. The release of formic acid, a chemical defense of the ants, is thought to help prevent parasite infestation, decrease skin irritation, and self-stimulate. Some arthropods spread antibiotic secretions over their body to protect themselves from bacterial and fungal infections. Secreted lipids or fatty acids also help protect some mammals from the cold, by absorbing radiation and providing an additional layer of insulation. Similarly, frogs use lipids secreted from specialized cutaneous glands that are then wiped across the body surface to provide a barrier against evaporative water loss. For the majority of birds, the uropygial gland, or preen gland, is an important part of preening. The uropygial gland is found near the base of the tail and produces an oily substance that when distributed over the plumage via preening, helps waterproof the feathers and keep them flexible. Some preen gland secretions also possess antimicrobial properties. Secretions distributed over the body surface via grooming are also considered to serve as chemical signals (“► [Pheromone](#)”) during foraging, social, and courtship interactions among a range of animal taxa.

In addition to maintaining the form of the integument itself, the groomer may also remove foreign material (i.e., dirt, ectoparasites, detritus, scabs, vegetative debris) from in or between the skin and its appendages (e.g., hair, feathers, and scales). Most animals are prone to various ectoparasite infestations, including lice, leaches, mites, and ticks. Ectoparasites can

negatively effect their host in a variety of ways, including blood loss, reduced appetite, nutritional deficits and weight loss, and an increased prevalence of disease transmission. Parasite infestations have a negative impact on individual health and fitness by reducing survival and reproduction, so any means by which parasite removal is possible, in this case grooming, is likely to have come under strong selection. By removing dirt and ectoparasites, grooming increases the cleanliness of the pelt and increases individual health. Indeed, grooming rates are predicted by intensity of parasite infestation and are higher on body regions of higher parasite load, and grooming is also more prevalent among populations that live in geographic regions of high parasite risk. Allogrooming tends to be directed toward body regions that cannot be reached by self-grooming. As well as maintaining the pelts form and keeping the fur clean, it feels good to be groomed. Being on the receiving end of grooming has been associated with endorphin release, lowered heart rates, and reduced social anxiety and baseline stress levels. Grooming, however, also comes with its associated costs. Grooming is a time-consuming activity and occurs at the expense of other behaviors critical for survival and reproduction, namely, vigilance for predators, feeding, resting, and mating. Allogrooming may also increase the transmission of disease and infection between social partners, which can have a negative impact on individual fitness. Repetitive self-grooming, self-scratching, yawning, and body-shaking are all forms of displacement activity, behaviors that reflect the emotional status of an individual at times of internal conflict and social uncertainty. Excessive self-grooming, or plucking, which can lead to baldness, can be seen across a wide range of animal taxa, most notably in birds.

Allogrooming is thought to have evolved primarily for its hygienic function. In some animal taxa, however, allogrooming occurs at rates that far exceed the amount needed for parasite removal alone, and can sometimes occur in the absence of parasite infestation all together. If allogrooming were to serve a purely utilitarian function, one

would expect grooming rates to be positively predicted by body size, since the greater surface area associated with larger body size would require more grooming effort to clear it of dirt and ectoparasites. Evidence that grooming rates are positively predicted by group size, but not body size, however, has led to the belief that allogrooming is not solely limited to a utilitarian function, but also serves an important role in social bonding. Social grooming is seen across a diverse range of animal taxa. Social grooming is used to service social relationships among group members. Social relationships help alleviate the negative consequences of within group competition, and individuals more socially integrated into their group experience improved health, longevity, and offspring survival, compared to those more socially isolated. The social functions of grooming are discussed in detail in the entry “► [Social Grooming](#).”

## Introduction

The distinction of animal species between solitary and group living is rather artificial (Krause and Ruxton 2002), as even animals that spend the vast majority of their time alone engage in social interactions and/or join a group at some point in their life (Tinbergen 1953), for example, when mating, during parental care, or when a large food source attracts many conspecifics. Definitions of group living differ based on the type and frequency of social interactions that group members are expected to display with one another to form a “group,” the degree of cohesion and coordination between group members, and the stability of the group over time (Krause and Ruxton 2002). Terminology also varies depending on the taxonomic group or type of social interactions between group members. For example, a social group of fish is called a “shoal” and scientists use the term “community” to define a group of chimpanzees. However, virtually every definition of group living accepts that animals need to show some degree of spatial proximity over time to form a group. Wilson (2000, p. 585) defined a group as “any set of organisms, belonging to the same species, that remain together for a period of time while interacting with one another to a distinctly greater degree than with other conspecific organisms.”

## Evolution of Group Living

Solitary life is considered the ancestral state and group living has probably evolved independently in various taxa. Several different hypotheses have been proposed to explain the evolution of group living, some that can potentially apply to any taxonomic group and others that are more taxon-specific. Wilson (2000) argued that the prime driving forces of social evolution are phylogenetic inertia and ecological pressure; the evolution of sociality would thus result from the constraints imposed by phylogenetic inertia on genetic response to ecological pressure. Phylogenetic inertia refers to the constraints of evolutionary change (Blomberg and Garland 2002) and can

be observed when there is a mismatch between ecological conditions and behavioral responses. For example, phylogenetic inertia has been proposed as a factor determining why current ecological conditions do not explain differences in social style in the genus *Macaca*. Theories on what ecological pressures favored the evolution of sociality consider the costs and benefits of group living versus solitary life for individual fitness. According to these theoretical frameworks, group living may have evolved independently in various taxa when, over evolutionary time, the benefits of group living for the inclusive fitness of an individual outweighed the costs. Different theories have proposed a range of different ecological pressures as the main determinants of social evolution. These different ecological pressures can be grouped into three broad categories: (a) foraging (and access to other resources such as water or shelter), (b) defense from predators, and (c) access to mating opportunities (including infanticide). Each of these ecological pressures can give benefits to individuals living in groups (Majolo et al. 2008). However, group living animals can also incur in some costs when, for example, a group becomes so large that food competition within the group becomes so intense that its costs outweigh the benefits of group foraging (e.g., protection from predators). Although group size is expected to vary within species, depending on the local ecological conditions of a population or group, each species/population is expected to have an upper and lower limit of “tolerable” (or “optimal”) group size. If a group falls below the lower limit, or it grows above the upper limit for the species/population optimal group size, the costs of group living are expected to outweigh the benefits and the animals in the group can, respectively, join another group or fission into two or more groups.

### Foraging

Group living (or living in larger groups) allows group members to access and/or defend valuable resources at the expenses of solitary animals or smaller groups from the same or from different species (Packer and Ruttan 1988). Group-living predators, such as wolves and African wild dogs,

can catch large prey that they would not be able to capture if hunting alone. In the nonbreeding season, Harris’ hawks (*Parabuteo unicinctus*) form parties of two to six animals to improve their capture efficiency. Hawks in those parties also consume less energy per unit of time spent hunting. Pelagic dolphins (*Stenella longirostris*) act together to force their prey into a smaller space so that increased prey density improves capture rate. In the social spider *Anelosimus eximius*, communal living favors group defense and protection of food sources. In the blue tang surgeonfish (*Acanthurus coeruleus*) group foraging results in better defense of food from damselfish (*Stegastes dorsopunicans*) and increased feeding efficiency (i.e., increased bite rate on algal mats). Finally, the larger a group of lions (*Panthera leo*) the greater their chance of defending their prey from spotted hyenas (*Crocuta crocuta*).

Searching the environment for food is time-consuming and potentially dangerous in terms of exposure to predation risks, particularly for solitary animals. Group living gives animal the possibility to gather information from other group members, or from members of other species for mixed-species associations (i.e., two or more species moving together with some degree of coordination for a given amount of time). Such information can be about the location of food, the amount of food available, the assessment of a habitat or area (its suitability, richness, or perceived risk), or the presence of predators nearby. The advantages of foraging in groups have been shown in various taxa. Goldfish (*Carassius auratus*) and minnows (*Phoxinus phoxinus*) locate food more rapidly with increasing group size. Group foraging allows bats (*Rhinopoma microphyllum*) to increase their efficiency on prey detection and capture by maintaining high-levels of group density and conspecific interference.

Additional benefits of group living, not necessarily associated to foraging, are thermoregulation and reduced costs of movement. Group living allows animals to huddle together when cold, to maintain the necessary body temperature and improve thermos-regulation, with significant benefits on energy expenditure. Moreover, moving in a group allows animals to take turn at the front or

back of the group, and to travel behind other individuals reducing resistance of the medium and energy expenditure. This is particularly beneficial for migratory birds or fish.

Group living may also involve some potential foraging costs for individuals, in the form of increased within-group food competition, depending on the amount and distribution of resources. Food competition is differentiated into “contest” and “scramble” competition. Contest competition occurs when animals aggressively interact with one another to gain access over the contested resource. Such interactions may range from aggressive displays from a distance to physical contact resulting in injuries or death, and the winner of the interaction may have either full or prioritized access to the contested resource. Scramble competition describes the scenario where animals are depleting a resource without engaging in a direct contest with other animals who are similarly interested in accessing and using that same resource. For example, scramble competition would occur when two animals are feeding on the same fruiting tree but at different times, that is, without encountering each other on/near the contested resource. Therefore, even if animals do not monopolize and aggressively exclude other group members from a food patch, in larger foraging groups animals have a lower amount of food potentially available per capita, other things being equal (e.g., interindividual difference in feeding efficiency). The degree of within- and between-group food competition determines the optimal group size for a population or species. In a comparison of the ecology and behavior of 75 species of African antelopes, researchers found that species that are described as selective feeders form smaller groups than the species that are unselective feeders. Selective feeders are species where animals feed on resources that are that are difficult to find, and/or patchy in time or space, that is, species where the risk of food monopolization and competition is high. In those species, therefore, smaller groups result in lower within-group food competition. Conversely, in species with unselective feeding the cost of within-group competition is lower and thus group size is greater.

Another potential benefit/cost of foraging in groups is klepto-parasitism, where an animal steals food from another individual. Klepto-parasitism is particularly frequent when the energy required to find food is high: such a scenario makes klepto-parasitism highly beneficial for the “thief” (as that animal gets food without incurring in the energy expenditure necessary to obtain it) and costly for the target. Klepto-parasitism is common in seabirds between and within species, especially during communal nesting.

Increased risk of infection and of transmission of parasites and disease may pose significant ecological pressure on group living animals (Alexander 1974). Animals living in groups often interact and are in close proximity with other individuals so the risk of disease/parasite transmission is higher than for solitary animals. For example, in a ground-dwelling avian species, the bobwhite quail (*Colinus virginianus*), there is a positive association between flock size and intensity of infection by parasitic helminths. Moreover, parasite infection in European bee-eaters (*Merops apiaster*) decreases with increasing inter-nest distance. A high parasite burden imposes significant fitness costs to animals, such as slow growth, high winter mortality, and reduced reproduction. The extent to which the risk of parasite/disease infection constrains sociability and group size is still unclear.

### Defense from Predators

One of the main advantages of group living, in relation to predation risk, is that animals in groups are more likely to spot a predator (so-called many eyes effect) than solitary individuals. Many group living species use alarm calls and other displays to signal group members about the presence of a predator. In some species, e.g., meerkats (*Suricata suricatta*), group members take turn in performing the role of “sentinels” while the rest of the group is resting or feeding. There is a positive relationship between group size and reliable predator detection. For example, in the banked killifish (*Fundulus diaphanus*) the occurrence of false alarms is reduced in larger groups. Moreover, common starlings (*Sturnus vulgaris*) and laughing

doves (*Streptopelia senegalensis*) in flocks respond more quickly to a predator model than single birds. In mammals, the distance at which long-tailed macaques (*Macaca fascicularis*) detect predators increases with their party size. Thus, the many eyes effect allows an individual forager to spend less time on antipredator vigilance and more time on other activities, and the more so the larger the group.

Once a group living species detects a predator, it can either escape a predator attack or mob the predator. Mobbing behavior occurs when potential prey join forces together to aggressively attempt to drive the predator away. Mobbing has been observed in a range of species including, for example, in crows mobbing eagles or baboons mobbing leopards (Caro 2005). As demonstrated in the Antarctic terns (*Sterna vittata*), mobbing against South Polar skuas (*Catharacta maccormicki*) significantly reduces the costs of predation risk. Mobbing is a cooperative behavior that may depend on reciprocal altruism: in the pied flycatchers (*Ficedula hypoleuca*) birds are more likely to help their conspecific neighbors mobbing a predator if those neighbors have helped them previously.

Group living helps animals escaping predators' attacks through a "dilution effect" whereby the larger the group of prey the more difficult for a predator to focus on a single prey and the less likely is for a single animal to be caught by a predator. There is an upper limit to the number of prey that a predator can handle or consume during a certain period. Therefore, groups that maximize the synchronization of their activities and their coordination of movements can benefit the most from the dilution effect, as animals in those groups are less likely to be separated from the rest of the group. For example, redshanks (*Tringa totanus*) who live in a larger flock have lower probability of being killed by raptors than those living in a smaller flock. Reproductive synchrony can be a strategy for reducing predation rate on vulnerable offspring through a dilution effect. In snowshoe hares (*Lepus americanus*) predation risk is negatively related to the number of synchronous litters. Similarly, the mortality of pronghorn (*Antilocapra americana*) fawns during

the peak fawning period is lower than for pronghorns born during the nonpeak period.

Even though larger prey groups are more exposed and conspicuous to predators, the increased risk of being detected is outweighed by the decrease of the individual likelihood of being preyed upon as the group becomes larger. The interplay between the risk for a group to be detected by a predator and for a group member to be attacked by a predator determines the benefits/costs of group living for an animal in relation to predation. For example, although larger groups of stream-dwelling trichopteran pupae (*Rhyacophila vao*) were more likely to be attacked by planarian predator (*Polycelis coronata*) than smaller groups, the predation risk for each pupa was still lower than for those pupae who were living in smaller groups. Finally, animals in a group are not all equally likely to be attacked, as predators prefer to target individuals who are weak, ill, or slower, and/or those who are at the periphery of the group. For example, predators like the bluegill sunfish (*Lepomis macrochirus*) preferentially attempt to hunt individuals who do not coordinate their movement with the rest of the group. Therefore, there may be competition between group members over which position (center or periphery) each animal should take in the group when a predator is nearby.

### Access to Mating Opportunities

Group living animals are more likely to get access to a mate than those who live solitary and so the former has more opportunities to compare potential mating partners and for mate choice. In mammals living in groups composed of multiple males and females, concealment of estrous and estrous synchrony among group females reduce the risk of sexual coercion by males (a significant risk for females, especially in species with pronounced sexual dimorphism in favor of males), increase sperm competition, paternity uncertainty, and female mate choice.

Leks, or mating arenas, are communal mating grounds where males gather to engage in competitive displays to signal their strength to females, as the competitive ability of males in lekking species is a measure of genetic quality. For females, the

lek allows effective assessment of each male's quality and strength, and it thus provides excellent opportunities for female mate choice. Females who choose the most powerful male in the lek have lower risk of harassment from other males. Lekking is observed in a large number of species and it allows strong, dominant males to maximize their reproductive success. Several models predict that the ability to monopolize females by high-ranking males can be affected by the extent of disturbance received from low-ranking males in a lek. Therefore, lower-ranking males should have greater reproductive success in larger leks, which attract more males, and/or under a wider spatial distribution of females. Moreover, related males can join forces and out-compete unrelated males when the inclusive fitness benefits gained through reproductive success of relatives are greater than the benefits of reproduction to direct fitness (Kokko and Lindstrom 1996).

In several mammals, infanticide is a strategy used by males to increase their reproductive success. In these species, males can kill infants who they are unlikely to have sired so that females can resume estrous and become ready to resume mating. Infanticide is a potential risk for both solitary and group living species, as, for example, it may be observed in species where solitary lactating females with their infants move within the home range of a male. However, infanticide is a particularly beneficial strategy for subordinate or immigrant males, and risky for females, in species where multiple females are present in the same group and where females synchronize their estrous. In these species, several infants of roughly the same age can be present, making the group particularly "attractive" for immigrant infanticidal males who attempt to enter that group at the top-ranking position. Similarly, a group male who has a subordinate position but manages to outrank the dominant male (who sires all/most of the infants) can kill the infants to mate with the group females. Group females employ counter-strategies to avoid or limit the risk of infanticide. In some nonhuman primate species, for example, group females form alliances with one another to prevent immigration of adult males into their group. Moreover, in baboons (*Papio*

*cynocephalus*), group males protect lactating females from potentially infanticidal males. During intergroup interactions, dominant male black howler monkeys (*Alouatta pigra*) show more aggressive behavior towards potentially infanticidal intruders when vulnerable offspring are present.

## Interspecies Variation in Grouping Patterns, Mating Strategies, and Social Structure

The large number of animal species, especially those foraging nocturnally or underground, such as some marsupials and insectivores, tend to be solitary. There are, however, several exceptions to this pattern; badgers, for example, are a highly social species but are often active at night and spend the day in burrows. Many group living species are diurnal, possibly as a response to the increasing predation risk in open environments and during the day (van Schaik 1983). Group living animals inhabit a wide variety of habitats, use different ecological niches, and are exposed to a range of ecological pressures. Indeed, extensive differences exist between and within group living species and several nonmutually exclusive factors can be used to describe such differences (Clutton-Brock and Harvey 1980). These factors include mating patterns (monogamy or promiscuity), group size and composition (i.e., whether animals of both sexes and/or of every age class are present in the group or not), the rate of gene flow within and between groups, kin and dominance relationships, and social bonds between group members. In the second half of the last century, researchers have spent a growing amount of effort to try and extrapolate general patterns on the social organization and structure of group living species based on the factors described above and in response to different ecological conditions (Crook and Gartlan 1966). The resulting socioecological models attempt to explain within and between species differences in grouping patterns and explain how these may have emerged in response to the cost and benefits of group living linked to a specific ecosystem (Crook et al. 1976).

## Eusociality

Eusociality describes a social organization where individuals engage in cooperative care of the young; there are different generations in the same colony and division of labor. Colonies of eusocial species are mainly found in social insects (ants, wasps, bees, and termites) (Wilson 2000), but also in some spiders, coral-reef shrimps, and mammals. In eusocial colonies, members are often divided into two castes, one composed of the reproductive individuals and the other of the (partially) nonreproductive individuals; members of the nonreproductive caste gain inclusive fitness benefits by helping their genetically related and reproductively active members of the colony (Nowak et al. 2010). Three main evolutionary pathways to eusociality have been proposed. In haplodiploid Hymenoptera, males are haploid (i.e., have an unpaired set of chromosomes) while females are diploid (two sets of chromosomes). Therefore, females are more closely related (they share 75% of their genes) in those species than females in non-haplodiploid species (who share 50% of their genes). This can facilitate the evolution of a sterile caste of females who gain inclusive fitness benefits by helping their reproductively active sampling to reproduce (Hamilton 1964). Boomsma (2007) argued that kin selection can favor the evolution of eusociality also in non-haplodiploid species, when inclusive fitness benefits for some individuals are comparable or greater than fitness benefits obtained via reproduction (Davies et al. 2012). A third hypothesis states that the formation of eusocial colonies is a response to intense competition with other colonies and/or predators that favored the evolution of a caste of soldiers.

## Monogamy

Among noneusocial species, groups composed of a monogamous breeding pair are found in various taxa, especially in insects, fish, birds, and mammals. The breeding pair often occupies a territory and their sexual bond can last for a single breeding season or for their lifetime. Even though living in pairs reduces the chances for females to elicit sperm competition and for males to sire a large

number of females, biparental care is considered as an essential advantage of pair bonding. In species with this social organization, the cost of reproduction is too high for a female to sustain it without the help of their breeding pair so males maximize their reproductive success by providing parental care. In marmosets and tamarins, for example, females often produce twins or triplets that are very heavy, relative to the body weight of the mother; thus, males are mostly responsible for carrying the infants around and for protecting them (Gubernick and Teferi 2000). Similarly, male zebra finches (*Taeniopygia guttata*) contribute as much as females to the rearing of the infants. After artificially removing male snow buntings (*Plectrophenax nivalis*), females who were left alone could only rear fewer young with lower body mass than the females who did not lose their male partners. Monogamous pair bonding could also enhance the ecological defensibility of females and protect their offspring from infanticidal competitors. Monogamy is much more common among birds than mammals: in birds, approximately 90% of species are monogamous. However, advancements in DNA analysis are showing that many species of birds that were once considered as monogamous are in fact promiscuous. Females may mate with more than one male to increase the number of males who contribute in feeding the nestlings. Similarly, males may be able to mate with two females and raise the two broods when food is abundant. Extra-pair paternity also exists among extensively monogamous mammals, such as prairie voles (*Microtus ochrogaster*), alpine marmots (*Marmota marmota*), fat-tailed dwarf lemurs (*Cheirogaleus medius*), and white-handed gibbons (*Hylobates lar*). In mammals, although paternal care is a strategy to maximize reproductive success, it is not considered to be a precondition for the evolution of social monogamy. According to Lukas and Clutton-Brock (2013), the evolution of social monogamy is favored when there is intense feeding competition, intolerance among females, and low demographic density, because males are incapable to monopolize more female partners under these circumstances.

### Cooperative Breeding

Cooperative breeding is a reproductive system in which some group members do not reproduce (for part or all of their life) but provide alloparental care to help the breeding individuals (Arnold and Owens 1998). Together with eusocial insects, cooperative breeding is found in birds and mammals. Usually the helpers, sometimes called auxiliaries or co-breeders, may be nonbreeding subadults or adults who are related to the offspring's parents; thus, helpers gain inclusive fitness benefits by providing parental care (Stacey and Koenig 1990). The helping behavior can involve not only incubating and providing food for the infants, but also defending nest and protecting young from predators. In these cooperative groups, sometimes the older offspring remain in the group until they reach adulthood and/or until they find a breeding partner, and help their parents raise the next generation of offspring, thus forming a family unit similar to what found is in many human societies. Cooperative breeding is particularly beneficial in altricial species, where young individuals are born in an underdeveloped state and need extensive care (Wilson 2000), and/or when food is scarce. Among pied kingfishers (*Ceryle rudis*), for example, under severe food shortage the presence of helpers is significantly and positively related to infant survival. In mammals, a high level of relatedness between group members is one of the driving forces in the evolution and maintenance of cooperative breeding (Lukas and Clutton-Brock 2013). Moreover, alloparental care can help inexperienced individuals to "learn to be parent" or to gain social benefits such as agonistic support. For example, female rhesus macaques (*M. mulatta*) provide alloparental care to their higher-ranking sisters in exchange for food tolerance and alliance formation.

### Polygamy

Another type of group living is where a single individual of one sex monopolize several individuals of another sex. A classic example of this type of group living is the uni-male groups (harems) of gorillas. Both polygyny (a male with multiple

females) and polyandry (a female with multiple males) have been observed (Shultz et al. 2011). Three main hypotheses have been proposed for the evolution of polygyny, resource defense polygyny, female defense polygyny, and male dominance polygyny (Emlen and Oring 1977). Resource defense polygyny should appear when a male attempts to attract females by occupying an area or territory with abundant and high-quality resources that would be available for females. This form of polygyny mainly occurs in habitats where resources are unevenly distributed and the number of females attracted by a male is often dependent on the quality of the area a male occupies and can defend from other males. Among shell-brooding cichlid fishes (*Lamprologus callipterus*), territorial males transport and accumulate shells as substrates for females to spawn in them; the more shells the male accumulates, the more females the male mates with. Female defense polygyny appears when males try to join in a group of gregarious females and fight with other males to monopolize the females in the group; this is also defined as female guarding polygyny. In these species, related females forage and move together, while males leave their natal groups before their sexual maturity and join other female groups during the breeding seasons to mate. This pattern is observed, for example, in African elephants (*Loxodonta africana*) and sperm whales (*Physeter macrocephalus*). The male dominance polygyny is found in species where there is high synchronization of reproductive activity among females. Males aggregate in competition arenas to fight other males and display their strength to females (see lekking behavior above). Dominant males can mate with several females but usually do not provide parental care; females are responsible for nesting, incubation, and feeding of the nestlings. For example, in the lekking white-bearded manakins (*Manacus manacus*), males who engage in more aggressive displays mate with a larger number of females than less aggressive males. After mating, females leave the lek and start nesting whereas males stay and compete to mate with other females.

### Mixed-Sex and Multilevel Societies

Multimale-multifemale groups are composed of various individuals of both sexes. The presence of multiple females attracts males and, in this species, a positive correlation exists between the number of males and females in a group. The larger the number of females, the less likely dominant males are to monopolize mating. This is particularly true for seasonal breeding species and where females synchronize their estrous and increase the importance of female mate choice and sperm competition. Multimale-multifemale groups are particularly common among Old World monkeys like baboons and macaques (Wrangham 1980).

Multilevel societies are characterized by a discrete stratification of one or more stable social units (i.e., layers such as basic social unit and clans) within the group. In the basic form of multilevel societies, individuals are grouped into a basic social unit, often composed of an adult male and one or more adult females plus their dependent infants, and these units can be grouped into a larger social layer (e.g., a herd). Multilevel societies are common in mammals and can be observed, for example, in elephants, cetaceans (bottlenose dolphins, *Tursiops* spp.), plains zebras (*Equus burchelli*), and some nonhuman primates (e.g., gelada baboons, *Theropithecus gelada*). Multilevel societies have probably emerged independently in different taxa in response to a combination of environmental and demographic factors. The social organization of plains zebras, which is supposed to be one of the simplest forms of multilevel society, is composed of only two tiers where several basic breeding units form a large herd. The formation of herds is due to the presence of large and even food resources (grass) and protection from predators. In nonhuman primates, elephants and cetaceans, multilevel societies have a more complex hierarchical structure. For example, in some primates, such as gelada baboons, hamadryas baboon (*P. hamadryas*), proboscis monkeys (*Nasalis larvatus*), and snub-nosed monkeys (*Rhinopithecus* spp.), there is a complex network of social relationships within and between each social layer, which has been termed modular or nested organization. In

hamadryas baboons, societies are hierarchically structured with several embedded levels: breeding units, "clans" (where often either the males or the females are genetically related to, or have social bonds with individuals of other breeding units within the clan), bands, and troops. The bands are often followed by males who are immature or young and affiliated with some breeding units. The troop can consist of hundreds of animals who move in a rather coordinate way. In snub-nosed monkeys, societies are structurally similar to those of hamadryas baboons. However, independent breeding units are territorial and occupy a certain home range; the degree of tolerance, proximity, and coordination between breeding units varies with familiarity between members of the different units and with the quantity of food available. The threat from conspecific individuals is thought to be the selective force of multilevel societies in nonhuman primates. The ancestral species lived in multimale-multifemale groups and a modular social structure emerged in response to competition between breeding units.

### Fission-Fusion

Fission-fusion societies describe group living species characterized by a flexible and dynamic social structure: individuals within the same fission-fusion society can join different parties for a variable amount of time (from a few hours to days); the composition of these parties can vary over time and parties can merge and split repeatedly so that rarely all individuals in a fission-fusion society are found together within a small area (Aureli et al. 2008). Fission-fusion societies are found in, for example, spotted hyenas, African elephants, dolphins, spider monkeys (*Ateles* spp.), and chimpanzees (*Pan troglodytes*). However, some degree of fission-fusion dynamics is found in virtually every group living species and particularly in species living in multilevel societies. Fission-fusion societies evolved as an adaptive strategy to the unpredictable distribution of resources, their patchiness, and the fact that food sources could not accommodate all animals within the society; parties reduce food competition between members of a society. In African elephants, kinship and resource availability affect

fission-fusion dynamics and individuals form different parties but the mother-calf pair remains a stable core unit. Fission-fusion dynamics are also affected by demographic factors. In communities of chimpanzees, for example, when the size of the community decreases, individuals form larger parties that are more frequently composed of both males and females than in large communities (where females often travel alone or with their dependent infant). Such a change in fission-fusion dynamics is explained by male reproductive strategies: in small communities, males are less likely to encounter and mate with females so they spend more time travelling and in association with females.

### Dominance

When resources such as food, shelter, or mating partners can be monopolized, animals living in group are expected to form a dominance hierarchy and compete to attain a dominant position. A dominance hierarchy is established and maintained through a series of aggressive/submissive interactions between group members, and animals that win most of the conflicts are dominant and those who lose are subordinates. Dominance networks can be described by three basic forms of hierarchy: linear, circular, and radial. A hierarchy is described as linear when group members can be assigned a dominance rank position that follows a linear order. For example, animal A is dominant over all the other group members, B is dominant over all the other group members but A, and so on. Linear hierarchies are common in insects, crustaceans, most birds, fish, and mammals (Wilson 2000). A circular hierarchy can be observed when, for example, A is dominant over B, B over C, and C over A. Finally, a radial hierarchy is observed when, for example, A is dominant over B and C, but B and C have no resolved dominance relationships and can equally win conflicts with one another. Dominance relationships are also described as steep or shallow along a continuous gradient. In a steep hierarchy, a dominant animal always (or most of the time) wins fights with a subordinate individual, provided no other individual is involved (i.e., the conflict is dyadic). In a shallow hierarchy, the

outcome of a dyadic conflict is context and temporally dependent, meaning that A may win some conflicts with B and lose some other depending on when, where, and over what resource they fight. The establishment of dominance hierarchy is an important factor that helps keeping a group stable and limits the risk of escalated aggression: subordinate group members tend to avoid dominant animals and so incur in a lower risk of aggression and injuries. Clearly, this is not the case if an animal is challenging the dominant position of another group member, and rank reversals often result in severe injuries and even the death of one of the contestants. Finally, dominance hierarchy can be very stable over time or change frequently over a short period of time, especially if group composition changes rapidly due, for example, to immigration, emigration, or deaths. What dominance position an animal can attain has a pronounced impact on access to resources: dominant animals typically gain more benefit (e.g., access to food) than subordinates that can result in fitness advantages (greater reproductive success). For example, dominant female spotted hyenas have a greater access to food in a competitive feeding situation than subordinates. In primates, high-ranking males have greater fecundity and mating success than low-ranking males (Majolo et al. 2012). However, counter-strategies from subordinates, such as sneaky copulations, can significantly reduce the differences in reproductive success between dominant and subordinate animals. For example, low-ranking male baboons may form alliances to try and outcompete dominant males and/or establish social bonds with females to increase their mating opportunities.

### Dispersal

In mammals, the spatial distribution and grouping patterns of females are considered key elements affecting male intrasexual competition, and females are the main ecological force driving social evolution (Wilson 2000; Emlen and Oring 1977; Lindenfors et al. 2004). Species living in groups may have sex-biased dispersal, whereby either males or females leave their natal group when they are about to reach sexual maturity and try to emigrate into other groups. In some species,

however, both males and females are equally likely to disperse. Dispersal and emigration from the natal group reduce the risk of inbreeding and affect the degree of genetic diversity within and between groups in the same population. In species with a sex-biased dispersal, members of the nondispersing sex often have several kin members in their group. For example, in primate species with a male-biased dispersal, like macaques, females form matriline composed of genetically related individuals and different matrilines compete to attain the dominant positions. This often results in the fact that all members of a matriline occupy adjacent rank positions and daughters attain the dominant position immediately below that of their mother. Moreover, in species with a male-biased dispersal, emigrating males may temporarily join bachelor groups and attempt to challenge males who have access to females.

### Social Bonds

One of the key features of group living is that animals can form social bonds with other group members. Social bonds can last for the whole life of an animal, especially between individuals of the nondispersing sex. The strength of these social bonds is affected by a number of factors: on average social bonds are often established between kin, familiar individuals, or individuals of similar sex, age, or rank. Social bonds are described by three dimensions: value, compatibility, and security. Value describes the benefits that individuals gain from the social bond. Compatibility describes the general tenor of the social bond and security measures the likelihood that a social bond would change over time. Social bonds can be established and maintained by a large range of species-specific behaviors, including allopreening, proximity, allogrooming, agonistic support, and embraces and physical contact. Animals sharing strong social bonds are more likely to support each other in conflicts with other group members, to tolerate each other near food source, to provide alloparental care, to gain mating opportunities or protection from predators. Ultimately, social bonds give fitness benefits to animals (including humans): individuals who have a larger or stronger network of social bonds survive

longer, have more offspring, a lower risk of stillbirths, more resilience to stress, and/or greater emotional stability (Dunbar 1998).

### Intraspecies Variation in Grouping Patterns, Mating Strategies, and Social Structure

With the growing amount of research on different populations, evidence is building that extensive differences in social dynamics exists within species. These within-species differences may be observed within a group, for example, in response to seasonal changes (e.g., rainy vs. dry season) or to unexpected events that change the habitat (e.g., a tornado). Moreover, within-species differences can also occur between populations of the same species and be more persistent over time. In guppies (*Poecilia reticulata*), populations living in areas where predation risk is high tend to form larger size shoals than populations where predators are scarce. Guppies appear to be flexible in their group dynamics and can rapidly adjust to new ecological conditions. For example, moving guppies from areas with high predation risk to predator-free streams rapidly decreases their tendency to shoal but they increase their shoaling behavior if moved back to areas with many predators. Similarly, in years when the population density of leopards is high, chacma baboons (*P. ursinus*) tend to forage in larger subgroups, and interindividual distances between group members during foraging are small. The same flexible responses may be observed for food competition. In a cyprinodontid species, the Japanese medaka (*Oryzias latipes*), when food resources are abundant individuals show high level of social tolerance and avoid consuming energy on conflicts with other group members; conversely, they increase conflicts over food when resources are scarce.

More permanent differences within species may be observed. A classic example is represented by the group dynamics of the chacma baboons. In some groups and populations baboons form one-male units whereas in other populations they form multimale-multifemale groups. These differences

in grouping patterns also change the behavior of baboons. Males living in one-male units are more vigilant and intervene in conflicts between their group females more frequently than males in multimale-multifemale groups. Differences within species in their grouping patterns may have fitness consequences. Red howler monkeys (*A. seniculus*) can live in both one-male units and in multimale-multifemale groups. Juvenile females have a higher mortality in multimale-multifemale groups than in one-male units, probably because they receive more aggression from unrelated males in multimale-multifemale groups. This difference in aggression received results in the fact that female survival is greater in one-male units than in multimale-multifemale groups.

## Conclusion

A clear distinction of taxa in terms of their grouping patterns is complicated by the flexibility of the social dynamics of taxa across seasons or populations. Under some ecological conditions (e.g., during the mating season or in the presence of a rich food source), individuals from a solitary species can be found in large aggregations in a small area. At the same time, animals usually living in groups can spend significant amount of time far away from the rest of their group, for example, when feeding or giving birth. Group living can be described by a series of “layers,” interconnected with one another, describing the mating and ranging patterns: type, strength, and size of the kin and social relationships; and the dispersal patterns and dominance style of the individuals in a group. The occurrence of these layers significantly varies across species as well as between populations or within the same social group across the seasons. Clearly, the flexibility and complexity of social dynamics is not uniquely human but is observed in many, distantly related taxa. Such flexibility and complexity represent a challenge for scientists, because it requires a stronger effort to study a large number of taxa instead of concentrating on just a few model taxa. At the same time, such flexibility and complexity of social dynamics represent an

opportunity to investigate the complex patterns and history of social evolution in the animal kingdom.

## Guesser-Knower Paradigm

Christopher Krupenye  
Department of Developmental and Comparative Psychology, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany

## Definition

Experimental procedure designed to investigate organisms' understanding of others' mental states, particularly discrimination of knowledgeable vs ignorant informants, in a cooperative-communicative context.

## Introduction

Humans are highly skilled mind readers; that is, we have the ability to think about others' internal mental states, such as desires and beliefs. This skill is known as theory of mind or mind reading. Theory of mind informs our attempts to interpret, predict, and even manipulate others' behavior and thus is central to much of our social interaction, including our strategies for communication, cooperation and competition, empathy, and deception. For several decades – since Premack and Woodruff (1978) asked the seminal question, “Does the chimpanzee have a theory of mind?” – researchers have been attempting to determine whether this critical human skill is unique to our species. Over the years, a variety of elegant paradigms have been developed in the service of this effort. Early among them was the guesser-knower paradigm.

## Guesser-Knower Paradigm

Povinelli et al. (1990) designed the guesser-knower paradigm to test whether humans' closest relatives, chimpanzees (*Pan troglodytes*), were capable of modeling others' perspectives. Specifically, the authors wondered whether chimpanzees could correctly infer whether human experimenters were knowledgeable or ignorant of the location of hidden food based on whether the experimenters had witnessed the food being hidden.

In the original study, the chimpanzees watched as one experimenter, the knower, hid food behind a barrier, in one of four cups. Thus, although the apes could not see where the food was hidden, they were aware that it had been hidden and that the knower had performed this act. A second experimenter, the guesser, waited outside of the room until the baiting was complete. Once the guesser had entered the room and both experimenters were positioned behind the four cups, each pointed to a different cup. The knower always pointed to the correct cup, and the guesser

always pointed to one of the empty cups. The chimpanzee was then allowed to choose one of the cups. If she chose the knower's cup, the knower gave her the food beneath. If she chose any other cup, the knower revealed the food under his cup and the subject received nothing.

The logic behind the guesser-knower paradigm is that if chimpanzees (or other species) recognize that the knower, but not the guesser, has knowledge of the food's location, they should selectively follow the knower's points to find the hidden food. Importantly, the roles of the two experimenters were alternated across trials so that the subjects couldn't solve the task by simply learning which of the two experimenters reliably indicated the correct food location. Moreover, in a subsequent transfer phase, the procedure was modified in several key ways in order to control for some low-level explanations. Both the guesser and the knower remained in the room behind the apparatus, the baiting was performed by a third experimenter, and the guesser wore a paper bag over his head during baiting so that he remained ignorant of the food's location.

All four chimpanzees in the study quickly learned to choose the cup indicated by the knower, and three continued to do so in the transfer phase. Povinelli et al. (1990) interpreted their results to indicate that chimpanzees may have correctly attributed knowledge of the hidden food's location to the knower and that they may understand generally that knowledge is acquired through seeing. However, the researchers also acknowledged that the subjects may have learned, at least in part, to identify the reliable pointer based on salient cues like whether he was present/absent or wore a paper bag during baiting.

## Other Species

The guesser-knower paradigm has been used to study the social cognitive abilities of several species besides chimpanzees. Povinelli himself tested human children (*Homo sapiens*) as well as rhesus macaques (*Macaca mulatta*), finding that 4-year-

old human children, but not 3-year-olds or macaques, could selectively use the communicative cues of the knowledgeable informant in order to find the hidden food (Povinelli and deBlois 1992; Povinelli et al. 1991). Notably, Flombaum and Santos (2005) later provided positive evidence for rhesus macaques' sensitivity to others' perspectives as well, by adapting Povinelli's paradigms for a competitive setting (similar to work with chimpanzees: Hare et al. 2000, 2001, 2006). Other researchers have also shown positive evidence of guesser-knower differentiation in domestic dogs (*Canis familiaris*) as well as common ravens (*Corvus corax*) (Bugnyar 2011; Catala et al. 2017; Maginnity and Grace 2014).

## Interpretation and Criticism

Findings from the guesser-knower paradigm have been interpreted in several ways. In line with the alternative raised by Povinelli et al. (1990), Heyes (1998) argued that chimpanzees in the original study simply learned to discriminate present vs absent and bagged vs unbagged experimenters based on consistent differential rewarding; that is, they were reading behavior, not minds. Following negative evidence of chimpanzee perspective-taking from several related studies and analysis of other works on animal theory of mind, Povinelli and colleagues also concluded that existing paradigms provided little evidence of mental-state attribution in chimpanzees (Penn and Povinelli 2007; Povinelli and Eddy 1996; Povinelli et al. 1994; Povinelli and Vonk 2003). More recent adaptations of the guesser-knower paradigm have included additional controls aimed at constraining the applicability of behavior reading explanations and strengthening the case for mind reading (e.g., Catala et al. 2017); however, the debate about whether any nonhuman animals can attribute mental states to others rages on.

Povinelli and Heyes have suggested that tasks like the guesser-knower paradigm fall short of demonstrating theory of mind because they cannot completely control for the possibility that animals are able to succeed solely by identifying statistical regularities in others' behaviors (i.e.,

behavior reading, e.g., distilling regularities into behavior rules like "agents orienting toward food during its baiting typically indicate the correct location of the food"), without needing to make any additional inferences about actors' mental states (Heyes 1998; Penn and Povinelli 2007; Povinelli and Vonk 2003). In contrast, others have postulated that, although individual behavior rules can be developed to explain animals' success in specific tasks, it is more parsimonious to assume that correct performance across diverse tasks is explained by a single unified theory of mind mechanism than by a suite of individually learned behavior rules (Call and Tomasello 2008; Hare 2011). These authors have also attempted to control for behavior reading in task designs by restricting behavioral cues that are available at the time of test (Hare 2011). Although consensus remains elusive, recent advances have contributed new methodologies that may help to tease apart competing explanations for the social cognitive skills of nonhuman animals (e.g., Buttelmann et al. 2017; Karg et al. 2015; Krupenye et al. 2016; Schmelz et al. 2011).

## Ecological Validity

Mechanisms aside, the guesser-knower paradigm and others like it – which test social cognitive skills in cooperative-communicative contexts – have also been at the center of discussions over which methods are most suitable for investigating the cognitive abilities of a given species. Although chimpanzees were successful in the original guesser-knower task, they performed more poorly in a number of subsequent tests that required them to communicate or interpret communication in cooperative contexts. Tomasello et al. (2003) argued that chimpanzees' failure may reflect a lack of ecological validity rather than a lack of theory of mind. That is, chimpanzees may respond inconsistently to pointing not because they cannot infer the knowledge state of the pointer but because they rarely communicate in such cooperative ways and thus do not understand the intentions behind the pointing. In contrast to cooperative-communicative settings, Hare

(2001) suggested, apes may be more skillful in competitive contexts, since it is likely in these contexts that apes most commonly employ the cognition under study. Indeed, experiments involving competitive contexts have provided much of the evidence for primates' most sophisticated social cognitive skills (e.g., Flombaum and Santos 2005; Hare et al. 2000, 2001, 2006; Kaminski et al. 2008; Karg et al. 2015; Krupenye et al. 2016; Schmelz et al. 2011). Interestingly, dogs excel in cooperative-communicative interactions with humans and, fittingly, have performed much better than primates in paradigms that rely on such contexts, like the guesser-knower paradigm (e.g., Catala et al. 2017; Maginnity and Grace 2014).

Although experimental contexts that are based on the challenges that animals naturally face in the wild may be best for capturing apparently sophisticated behavior, Povinelli and Vonk (2003) have also noted that these are the contexts in which animals may have had the most opportunity to learn behavior rules or for which they may have evolved innate mechanisms. A nuanced appreciation of ecological validity is thus necessary to design experiments for which animals are sufficiently motivated but which may be able to control for competing explanations.

## Conclusion

In conclusion, the guesser-knower paradigm is an experimental method developed by Povinelli et al. (1990) to test for theory of mind in nonhuman animals. Subjects face a pair of experimenters, one knowledgeable and one ignorant, who are indicating, correctly and incorrectly, respectively, which of several cups contains hidden food. Subjects could solve the task (i.e., choose the cup containing the food) by inferring the different mental states of the pointers (i.e., by mind reading) or by applying learned rules based on superficial cues to determine which actor is most likely to indicate the correct location (i.e., by behavior reading). Variants of the paradigm have been used to study social cognition in several species, including chimpanzees, rhesus monkeys, dogs, and common ravens.

Given that the paradigm relies on a cooperative-communicative context – one that is highly relevant for humans but not for all other species – the guesser-knower paradigm has been the topic of considerable discussion about ecological validity in experimental design. Apes may generally perform poorly in paradigms where they must interpret cooperative pointing because they rarely engage in such communication naturally, whereas human children and domestic dogs may have evolved specialized sensitivity to such cooperative-communicative cues. Thus, while the guesser-knower paradigm continues to be used to investigate social cognition in additional species, variation in performance across species must be interpreted with consideration of the ecological validity of the task to the individual species under study as well as the skills besides behavior or mind reading that may be foundational to success on the task. Combining this task with other existing tasks and novel ones aimed at addressing persistent alternative explanations (e.g., Heyes 1998; Penn and Povinelli 2007) will help researchers to determine the extent to which theory of mind is distributed among species other than humans and how it evolved.

## Habituation

Lori Reider  
Hofstra University, Long Island, USA

### Synonyms

[Desensitization](#); [Nonassociative learning](#)

### Definition

Habituation refers to a decrease in behavioral responding as a result of repeated exposure to a stimulus that is not attributed to sensory adaptation or motor neuron fatigue.

### Introduction

Have you ever been stuck on a noisy train car? When you first got on the train, you were probably annoyed by the conductor's loud voice over the speaker, the screeching sounds of the train as it stops and starts, or the person next to you yelling into her phone. However, as the ride went along, you probably stopped paying attention to the loud noises and may have forgotten about how annoying these noises were when you first boarded the train. This is an example of habituation. Habituation is the basic learning mechanism involving a decrease in responding with repeated

presentations of a stimulus (Domjan 2015). Habituation typically helps an organism ignore stimuli within their environment after learning a stimulus is not biologically relevant. From the example above, you might learn to ignore the train sounds or the person on the phone because they do not have a direct impact on you. You might even forget what the conductor said over the loud speaker or what the person was yelling about on the phone.

### Characteristics

A number of characteristics have been identified to explain how various factors impact the process and strength of the habituation process. Habituation can occur for varying amounts of time. Short-term habituation generally occurs when a response-eliciting stimulus is presented repeatedly within short intervals, while long-term habituation occurs with delayed but continuous presentations of a stimulus. Long-term habituation persists for longer periods of time and is generally attributed to enduring changes in learning compared to short-term habituation, which can dishabituate\* relatively quickly (Domjan 2015). Long-term and short-term habituation rely on different neural mechanisms, which can be attributed to the differences in the strength of habituation for each process (Squire 1987). Habituation can also be affected by time through spontaneous recovery\* (this is the identifying

characteristic of short-term habituation). If an organism is habituated to a stimulus and shows a decrease in responding, the response can at least partially recover with the passage of time (Thompson and Spencer 1966). Habituation can occur more quickly after the presentation of multiple stimulus-response presentations followed by spontaneous recoveries. Spontaneous recovery occurs faster for habituation resulting from high stimulation frequencies than habituation resulting from the presentation of low frequencies of stimulation (Rankin et al. 2009). The stronger the stimulus, the less likely habituation will occur, while weaker stimuli allow habituation to occur more quickly, showing a stronger decrease in the response. Habituation training that continues to occur after the response to a stimulus has disappeared or remained constant will result in slower recovery of the behavioral response (Thompson and Spencer 1966). Habituation for one response to a stimulus can also generalize toward other, similar stimuli. When presented with a separate (and usually stronger) stimulus, the stimulus will elicit the recovery of habituation (or decreased responding) to the original stimulus, also known as the process of dishabituation (Rankin et al. 2009). When the dishabituating stimulus is repeatedly presented to the organism, this can lead to a reduction in dishabituation, allowing the organism to habituate to the stimulus once again.

Habituation is not the only type of learning involving decreased responses to a stimulus.

A decrease in responding to a stimulus is considered habituation if it cannot be attributed to sensory adaptation or motor neuron fatigue. Sensory adaptation\* occurs when the sensory organs temporarily fail to respond to a stimulus. Sensory adaptation can occur when you enter a dark room and have trouble seeing because your eyes have not adjusted to the change in light. Motor neuron fatigue occurs when the muscles are temporarily unable to make the response to a given stimulus. Motor fatigue can occur if you are touching a vibrating object and you stop feeling the vibration because your motor neurons have weakened. Both of these concepts are not considered habituation, in part because they occur outside of the nervous

system. During habituation, the organism no longer responds but is still fully capable of sensing the stimulus and making the muscle movements required for the response (Domjan 2015).

Habituation can also be distinguished from motor neuron fatigue because habituation is *stimulus* specific. To rule out motor neuron fatigue, we look at different stimuli. If the organism does not produce a response to a stimulus, but can produce the same response to a different stimulus, the decline of the target response cannot be explained as response fatigue (Domjan 2015). A study by Epstein et al. (1992) illustrates this point. During this study, female participants were exposed to a repeated stimulus (tasting lemon or lime juice) for 10 trials. As the trials progressed, responding (amount of salivation) decreased over the course of 10 trials. At test, participants were exposed to a novel stimulus (the flavor they did not receive during the initial trials). After exposure to a novel stimulus, participants showed a significant recovery in responding (i.e., salivation). Results from this study showed that participants habituated to the repeated stimulus (i.e., the familiar flavor), and the salivation response could be restored with the presentation of a novel flavor.

Habituation can be distinguished from sensory adaptation because habituation is *response* specific. To rule out sensory adaptation, we look at different responses elicited by the same stimulus: If the organism does not produce a certain response to a stimulus, but still produces other responses to the same stimulus, the decline of the target response cannot be explained as sensory adaptation (Domjan 2015). For example, in the study by Epstein et al. (1992), repeated exposure to a flavor (either lemon or lime juice) resulted in a decrease in not only salivation but also a second response, namely, hedonic ratings. Had the authors observed a decline in only one of these responses (e.g., decrease in salivation, but not in hedonic ratings), their experiments would have also ruled out sensory adaptation.

Neuroscience research shows evidence supporting the role of neural mechanisms in the habituation process (see Kandel 2000; Thompson and Spencer 1966). While sensory adaptation occurs in the

sensory organs and motor neuron fatigue occurs in the effector muscles, habituation occurs within the nervous system\*. An organism fails to respond when habituation occurs due to changes in the nervous system, which prevent sensory neural impulses from reaching the motor neurons to perform a response (Domjan 2015). For example, Kupfermann and Kandel (1969) examined how behavior is modified by neuron activity by observing behavior in *Aplysia*, a species of sea snail. Their focus was on the process of sensitization\* – a fear response that emerges when an animal learns to produce strong responses to a neutral stimulus. Specifically, they examined the defense reflex, which involves gill withdrawal in response to aversive stimuli. *Aplysia* will withdraw their gills when they encounter a tactile stimulus to a specific part of the body known as the siphon. When an aversive shock was applied to the tail, *Aplysia* identified this as dangerous and evoked the defense reflex. However, when a neutral stimulus was applied to the *Aplysia*, the animal still produced a strong response to the stimulus. Results from this study suggest that *Aplysia* did not habituate to the stimuli but evoked strong defense reactions toward aversive (and nonaversive) stimuli. Kandel (2000) also showed that the process of long-term and short-term memory for sensitization differs. Long-term memory requires new proteins to be synthesized and is determined by the number of repeated exposures to the aversive stimulus. Repeated exposure to aversive stimuli with the implementation of a short delay between each presentation led to longer duration of memory for the aversive stimulus, lasting for days. In contrast, a single exposure to an aversive stimulus generated short-term memory of the stimulus, lasting only a few minutes. While research finds evidence linking habituation, learning, and neuroscience, more research is needed to fully understand *how* these mechanisms contribute to the learning process.

## Theoretical Support

The dominant theory for the underlying causes of habituation is known as the *dual-process*

*theory*. Proposed by Groves and Thompson (1970), the dual-process theory states that both increases and decreases in responding to a stimulus are guided by specific neurological processes. The theory suggests that habituation is guided by a process that decreases responding to a stimulus, while sensitization leads to increases in responding to a stimulus. Groves and Thompson suggested that each process occurs in distinct parts of the nervous system. While sensitization occurs in the state system, to determine the readiness of an organism to respond to a stimulus, habituation occurs in the S-R system, which allows an organism to make a specific response to a stimulus. The S-R system is activated for each stimulus eliciting a response while the state system is only activated in the presence of arousing stimuli. According to this theory, habituation and sensitization each attempt to control behavior, and the specific behavior elicited is determined by the net result of both processes (Domjan 2015). If a decrease in behavior emerges, this suggests that the strength of the habituation process is stronger than the strength of the sensitization process, leading to decreases in responding.

## Handicap Hypothesis

James P Higham

New York University, New York, NY, USA

## Synonyms

[Costly signaling](#); [Handicap principle](#)

## Definition

The hypothesis that in order to be honest, animal signals must be costly.

## The Handicap Hypothesis

The handicap hypothesis is an idea proposed in 1975 by Amotz Zahavi as a mechanism to explain how honesty is maintained in animal communication. The hypothesis proposes that in order to be honest, signals must have costs that are borne by signalers. Under this hypothesis, only high-quality individuals can afford to bear the costs of a high-quality signal, leading to honesty in communication. The hypothesis was critiqued by a number of authors through the 1970s and 1980s, including one of the preeminent theoretical evolutionary biologists of the era, John Maynard Smith. The handicap hypothesis remained largely discredited within the field until a game theoretic model was produced by Alan Grafen in 1990. In this model, a separating equilibrium was found in which the optimal strategy for signalers of different quality was to give a different signal type that reflected that quality. To achieve this outcome, Grafen associated cost functions with signals, with the costs experienced by signalers differentiating by signaler quality. This means that lower-quality signalers pay a higher cost than higher-quality signalers do to give a high-quality signal. Grafen (1990) added differentiating signal costs as a second condition to Zahavi's (1975) original concept of high costs to signalers, such that the handicap hypothesis is often now associated with

two conditions together: (1) that individuals pay a high cost to give their signal to maintain honesty (Zahavi's 1975 hypothesis) and (2) that lower-quality individuals pay a higher cost than higher-quality individuals do to give a higher-quality signal (Grafen 1990). Following this modeling, Grafen (1990) concluded that "Zahavi's major claims for the handicap principle are thus vindicated." In the years that followed, the handicap hypothesis became one of the best known and most commonly investigated hypotheses in the whole of evolutionary biology.

Interestingly, throughout the discussion of handicaps and the costs of signaling in the biological literature, there was a parallel literature in economics, which began with Spence (1973). Spence's model aimed to determine the mechanisms by which two graduating PhD students, one of whom is of low productivity and the other of high productivity, would honestly signal their respective productivities on the academic job market. Spence's model was later expanded to a more general condition, with continuous quality types, usually known as the Spence-Mirrlees condition. This series of work drew similar conclusions to the later model of Grafen (1990). However, this theoretical literature did not conclude that costs paid by signalers to give their own signal, i.e., condition #1 outlined above, proposed by Zahavi (1975), were necessary without applying further constraints. Since then, a range of models in the biological literature have drawn similar conclusions. As such, although Grafen (1990) concluded from his model that the finding of a separating equilibrium when differential signal costs are present supports the handicap hypothesis, other authors have concluded that this very same finding does in fact *not* support it. Under this latter interpretation, costly signaling models do not make any predictions about the costs that signalers must pay to give their own signals. They predict only that individuals give a signal that reflects their quality and that the costs associated with increasing signal expression beyond this are not worth the benefits of doing so. Individuals of high quality that give high-quality signals do not need to bear a cost to do so. The only cost required to enable this system to be honest is a potential

cost that low-quality signalers would pay to give a high-quality signal, should they choose to do so (to cheat). The conclusion from this is that signal costs experienced by signalers are not a *necessary condition* for honest signaling (i.e., condition #1, Zahavi 1975) above is unnecessary.

In addition, a second point to come out of these theoretical models is that signal costs experienced by signalers are also not a *sufficient condition* for honest signaling. Without condition #2, differential signal costs, a separating equilibrium cannot be found (Grafen 1990). Regardless of how costly it is for a high-quality individual to give a high-quality signal, a low-quality individual should also give that high-quality signal too, unless it experiences an additional cost for doing so. What makes individuals of all quality types give a signal that reliably reflects their condition is the differential signal cost. Thus Zahavi's (1975) hypothesis (condition #1 above) is not only unnecessary for honest signaling but is also not sufficient for honest signaling. Nonetheless, based on considerable confusion in the theoretical literature, and the subtleties of the above distinctions, it remains the most widely cited and considered explanation for honest signaling. Condition #2 above, introduced by Grafen (1990), is, in contrast, both necessary and sufficient for honest signaling.

A number of other types of models for honest signaling have been proposed in the evolutionary biology literature. One form is where there is alignment of interest between signalers and receivers, such that the optimal outcome for both individuals is the same. Under this scenario, theoretical models have shown that cheap honest signaling can evolve easily, given that there is no conflict between the signaler and receiver over the outcome of the interaction. Both individuals are selected to signal and respond honestly with no signaling costs required, beyond the efficacy costs associated with stimulating the receiver's sensory system. Another proposed mechanism is that of an index, in which individual signalers cannot cheat because signal expression is too tightly linked to anatomical or physiological condition. Under the index hypothesis, signals need not be costly to be honest. However, it is not clear that such a mechanism is distinct from that of a differential signal

cost scenario, as most interpretations of those models also do not predict that individuals must pay costs to give their own signal. Consistent with this, recent theoretical work on the evolution of index signals has supported the fact that indices can support cheap honest signals, essentially, by deriving a similar model and set of conditions (differential potential signal costs) to that seen in the costly signaling models (Biernaskie et al. 2014). Other proposed and commonly cited honest signaling mechanisms include punishment of cheaters, and reputation, whereby low-quality individuals who give high-quality signals are punished for it, and/or suffer a cost to their reputation. Because these are mechanisms by which lower-quality individuals experience higher costs for exhibiting high-quality signals than high-quality individuals do, they might be best seen as mechanisms for fulfilling the requirement of differential signal costs (condition #2 above).

Given the complex theoretical literature that has emerged on the topic of honest signaling, it has been difficult for empiricists to derive clear testable predictions from theory. Dozens, if not hundreds, of papers in animal behavior and evolutionary biology have tried to address the question of signal honesty by asking whether the signals that individuals exhibit are costly (i.e., testing condition #1 above). Typically, such studies have measured the signals that individuals express, while measuring physiological correlates of these signals, to ask if there might be “costs” associated with signal expression that might be involved in keeping signals honest. Results have been mixed. While some studies have found apparent costs associated with signal expression, others have not. Part of the reason for this might be that, as outlined above, it is not clear that costs should be expected in most cases given that they are not a *necessary condition* for honest signaling. Further, even if these costs are found, they do not necessarily indicate honesty because they are also not a *sufficient condition* for honest signaling.

A much smaller number of manuscripts have taken a different approach, testing condition #2 above – that of differential signal costs for higher- vs lower-quality individuals. Such studies have asked whether individuals pay additional costs to

give higher levels of signal expression than they actually exhibit, relative to individuals of higher quality. These studies have indeed often found success. For example, Madden (2002) found that when low-quality bowerbird males had their bowers artificially enhanced to resemble those of a high-quality male, they attracted more females, but provoked costly aggression from high-quality males. This cost is a differential signal cost – high-quality males do not experience such aggression for exhibiting a high-quality bower.

While there continues to be controversy and disputes around the nature of honest signaling, there seems to be broad theoretical agreement that differential signal costs are required for honest signaling when there is a conflict of interest between the signaler and the receiver. This means that high-quality signals must have costs for lower-quality individuals that are not present for higher-quality individuals. Because lower-quality individuals do not usually give high-quality signals in an honest system, such costs may be seen only when lower-quality individuals cheat, and give a high-quality signal. Empiricists are therefore on safest ground when undertaking experiments in which individuals are forced experimentally to exhibit increased levels of signal expression beyond those normally exhibited. Renewed interest in the theoretical basis for honest signaling in recent years will hopefully lead to broader agreement about the requirements for honest signaling, and also on more broadly agreed guidelines for empiricists as to what questions might most usefully be asked to address questions of signal honesty in animal systems.

## Definition

*Haplorhini* is one of two suborders in the order *Primates* and a type of eutherian mammal. Haplorhine (*Haplorhini*) primates consist of tarsiers, monkeys, apes, and humans.

## Haplorhini Taxonomy and Range

*Primates* are an order of eutherian (placental with advanced development before birth) mammal. Within the primate order, there are two suborders: *Haplorhini* (the haplorhines) and *Strepsirhini* (the strepsirhines). Haplorhines consist of tarsiers, monkeys, apes, and humans. *Haplorhini* can be further divided into two infraorders: *Tarsiiformes* (tarsiers) and *Simiiformes* (monkeys, apes, and humans). The *Simiiformes* can be further divided into two parvorders: *Platyrrhini* (platyrrhines or New World monkeys) and *Catarrhini* (catarrhines or Old World monkeys, apes, and humans).

Haplorhines live in most tropical and some temperate regions across the globe, in habitats ranging from tropical forest to woodland to savanna to temperate forest environments. While tarsiers live in tropical forests on islands off the coast of southeastern Asia, New World monkeys live in tropical forests in Central and South America (i.e., the “New World”). Old World monkeys live in a range of habitat types in Africa and Asia (i.e., the “Old World”), including the savanna (e.g., baboons, *Papio* spp.), tropical forest (e.g., mangabeys, *Cercocebus* spp.), cloud forest (e.g., colobus monkey, *Colobus* spp.), and Asian temperate forest (e.g., Japanese macaque, *Macaca fuscata*). Nonhuman apes live in tropical regions in Africa (e.g., gorilla and chimpanzee; *Gorilla* spp. and *Pan* spp.), southeastern Asia (e.g., gibbon and siamang; family *Hylobatidae*), and some islands of Indonesia (e.g., orangutan, *Pongo* spp.) (Estrada et al. 2017).

## Haplorhini Characteristics

In contrast to most strepsirhine species, which are solitary, nearly all haplorhines live in social groups consisting of two or more individuals of the same species (Dunbar 2010). The one exception is a catarrhine genus, the orangutan (*Pongo* spp.), which is semi-solitary. The gregarious social lives of haplorhines have influenced their cognitive adaptations. While all primates show a high level of ecological intelligence relative to other mammals, haplorhines perform better

on tasks associated with social intelligence compared to strepsirhines (Byrne 1995). Within the haplorhines, Great apes (family *Hominidae*: gorillas, orangutans, chimpanzees, and humans) show even greater social intelligence than monkeys (Byrne 1995).

Haplorhines are also characterized by increased reliance on vision and decreased reliance on sense of smell compared to strepsirhines. Catarrhines and platyrrhines have different nose shapes, with catarrhines having narrow nostrils that are close together and platyrrhines having wider nostrils that are further apart. Most haplorhines are diurnal (active during the day), although tarsiers and one genus of platyrrhine (owl monkey, *Aotus* spp.) are nocturnal (active at night). To reflect this tendency for diurnal activity, haplorhine eyes lack *tapetum lucidum* (a reflective layer causing eye shine at night) and have retinal fovea (pits in the retina which improve central vision in daylight) (Ollivier et al. 2004). Haplorhines such as catarrhines and one genus of platyrrhine (howler monkey, *Alouatta* spp.) also have full color vision, allowing them to better perceive habitat features in daylight (Liman 2006). In contrast, most other platyrrhines can see some color but cannot differentiate between red and green, while one genus (owl monkey, *Aotus* spp.) can only perceive shades of gray (Liman 2006).

Haplorhines live in both arboreal (tree-based) and terrestrial (ground-based) environments (Larson 2018). They travel through their habitats using a broad range of locomotory methods, including vertical clinging and leaping (clinging to tree trunks before leaping to other trees; e.g., tarsiers, family *Tarsiidae*), arboreal quadrupedal (walking along the tops of branches on four limbs; e.g., platyrrhines like howler monkeys, *Alouatta* spp.), terrestrial quadrupedal (walking along the ground using four limbs; e.g., catarrhines like baboons, *Papio* spp.), suspensory (using elongated arms to swing from branch to branch in trees; e.g., catarrhines like gibbons, *Hylobates* spp.), knuckle walking (walking along the ground using four limbs with weight put on the knuckles of the forelimbs; e.g., catarrhines like chimpanzees and gorillas, *Pan* spp. and *Gorilla* spp.), and bipedal locomotion (walking upright on two

limbs; e.g., catarrhines like humans, *Homo sapiens*; Larson 2018). While all living primates have strong grips and some degree of manual dexterity, platyrrhines and catarrhines are best at using their hands and feet to manipulate objects with control and accuracy (Liman 2006). Many platyrrhines have additionally evolved prehensile tails, which act as extra limbs to support body weight during travel and feeding in arboreal environments.

Haplorhines show a range of dietary adaptations, with the smallest (e.g., tarsiers and platyrrhines such as marmosets and tamarins, family *Callitrichidae*) being insectivores (showing preference for insects) or gummivores (showing preference for tree sap and gum), and larger haplorhines (e.g., larger platyrrhines and catarrhines) being frugivores (showing preference for fruit) or folivores (showing preference for leaves; Hohmann 2009). Some folivorous Old World monkeys (leaf monkeys, subfamily *Colobinae*) have specialized morphological adaptations for better digestion of cellulose, including sacculated stomachs and elongated intestines. In order to process a wide range of food items, primates have generalized dentition with different types of teeth adapted to perform different functions. These consist of incisors (used to cut food), canines (used to grip and tear food), premolars (used to tear and crush food), and molars (used to crush and grind food). Different groups of haplorhines have evolved different dentition. Tarsiers have a dental formula of 2.1.3.3/1.1.3.3 (i.e., 2 incisors, 1 canine, 3 premolars, 3 molars in each quarter of the upper jaw, and 1 incisor, 1 canine, 3 premolars, and 3 molars in each quarter of the lower jaw), most platyrrhines have a dental formula of 2.1.3.3. (i.e., 2 incisors, 1 canine, 3 premolars, and 3 molars in each quarter of the mouth), and catarrhines have a dental formula of 2.1.2.3 (i.e., 2 incisors, 1 canine, 2 premolars, and 3 molars in each quarter of the mouth).

## Conclusions

Haplorhines show greater reliance on vision and less reliance on sense of smell compared to other primates. Most are diurnal and group-living, with

greater social intelligence than other primates. They live in a range of arboreal and terrestrial environments worldwide and have a broad range of diverse locomotory and dietary adaptations.

## Haplotype

Shalini Roy Choudhury  
Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore, Karnataka, India

## Definition

*Haplotype* is a region or segment of chromosome comprising a group of genes in an organism that is inherited together from a parent. Haplotype is a contraction of the two words “haploid” meaning a single set of chromosomes and “genotype” meaning the genetic constitution of an organism.

## Main Text

The term haplotype can be variously defined pertaining to the genetic context. *First*, haplotype can signify an evolutionarily linked group of genes on a chromosome that has been transmitted as a single entity over thousands of years such as the mitochondrial or the Y-chromosome DNA. The human mitochondrial and Y-chromosome DNA are comprised of several evolutionary conserved *haplogroups*. A haplogroup arises from a distinct new single nucleotide polymorphism (SNP which are single base mutations) known as a unique-event polymorphism (UEP) that is carried by all the descendants. The new inherited mutation defines a particular haplogroup. Several

new SNPs do not make their way through the several thousands of years and those that do, form these haplogroups. To simplify, a new SNP arising now if gets descended over thousands of years will eventually form a new haplogroup. The same haplotype shared by several organisms can be used to trace the origin of the haplogroup to a specific individual or a specific clan of people. *Second*, haplotype can also mean a collection of a group of genes that gets inherited as a cluster over several generations of reproduction. *Third*, a specific meaning for haplotype can refer to a set of SNPs that always occur together. Haplotype can refer to a single SNP or a group of SNPs. *Fourth*, haplotypes can be identified as genetic signatures formed by a set of short repeat stretches of polymorphic DNA (regions of the DNA that are susceptible to genetic variability) known as *microsatellite markers* that get inherited as a linked region.

## Haplotype and Ancestry

Haplotypes get inherited from ancestors across the generations. Over several generations, only some haplotypes from a few ancestors tend to be inherited. These genealogical ancestors are also the genetic ancestors whose part of the genome is carried down to the future generations. More than 99% of our genealogical ancestors do not make it to being our genetic ancestors as the genetic information gets lost or modified by chance events during meiosis and processes of natural selection (Barton 2010). The genetic haplotypes also tend to get shortened over generations by random recombination. The exceptions to this rule of “loss of genetic information” are the mitochondrial and the Y-chromosome DNA, which are always inherited intact across their specific lineages. They have been routinely used for ancestry studies. The mitochondrial DNA is passed down exclusively by maternal inheritance, from the mother to the offspring. Only the female offspring passes this on to its next generation. The Y-chromosome DNA on the other hand is inherited by the son from the father and passed only to the male offsprings of subsequent

generations. These two are the exclusive cases unlike the autosomes that are a patchwork of genetic information from some ancestors. One question to consider is, if these ancestral haplotypes accumulate mutations over several generations would their ancestry still be recognizable? The simple answer to this is yes. The amount of mutation accumulated in the DNA over thousands of generations is very less due to it being a slow process. This would not hamper in detecting the ancestral haplotypes (Smolenyak and Ann 2004).

$$\begin{aligned} \text{Mutations accumulated} &= \text{Mutation rate} \\ ? & \quad \text{*number of generations} \\ & \quad \text{*length of base pairs} \end{aligned}$$

The human mutation rate is equivalent to one mutation in every 30 million base pairs per generation (Xue et al. 2009). These mutations assimilated over time in the genome contribute to its *genetic diversity*.

## Haplotypes and Genetic Disorders

Haplotypes are informative in the study of genetic disorders. Haplotype of any organism can be inferred from its genotype. *Genome-wide linkage analysis* is often used in the study of many Mendelian disorders (disorders caused by mutation in a single gene). Microsatellite markers present on all the chromosomes are typed to study *genetic linkage*. Linked DNA sequences that lie close together have lesser chance of recombination (a process that exchanges genetic material between homologous chromosomes) between them and tend to get inherited together. Genetic linkage analysis can be parametric (where the genotype and phenotype relation is known) or nonparametric. Logarithm of odds (LOD) score is frequently used in determining genetic linkage. It is a statistical test that examines the probability of obtaining a haplotype because of linkage or as a matter of chance. As a common rule, LOD score ( $Z$ )  $\geq 3$  means a higher probability of genetic linkage and lower values diminish the linkage probability. A LOD score of +3 indicates 1000 to 1 odds that the linkage does not occur by

chance. Although depending on the genetic complexity of inheritance of certain disorders, lower LOD scores can still be meaningful in the process of genetic linkage analysis. This approach is used in several genetic studies to identify the locus or the haplotype that segregates with the disorder in a family of several affected individuals. It can be used to determine the causative gene and mutation for the disorder in a family. This approach has been used as a powerful diagnostic tool to identify genes in many families with known and unknown genetic defects.

Haplotypes are useful in the study of complex diseases with genetic heterogeneity using another approach called the genome-wide association studies (GWAS). GWAS is used to study a large number of genome-wide variants in different individuals with a common trait to identify variants that associate with the phenotype. This kind of an association study is helpful in identifying new genes through variant association for complex disorders. One consideration in GWAS is phase resolution also known as haplotype estimation, to identify which chromosomes the mutations belong to. For example, in a two-phased heterozygote (A:G and T:C) 4 Mb apart, the appearance of A (position 1) and T (position 2) together all times does not assure that they are on the same haplotype. There could be several mutations within the 4 Mb region that could break up the haplotype. Finer the genotyping better the haplotype resolution. The GWAS technique has identified new candidate genes for bipolar disorder, rheumatoid arthritis, and coronary heart disease to name a few. Advances in the identification of new genes for rare genetic disorders are useful to advance the diagnosis and development of drugs and therapy for such disorders.

The International HapMap Project initiated in the year 2002 has developed a haplotype map of the human genome that catalogues the genetic variations associated with health, disease, drug and environment response (The International HapMap Consortium 2003). Although different populations do share haplotypes, their frequencies vary extensively. HapMap contains population-specific genetic profiling of variants to aid population-specific GWAS studies.

Studying shared haplotypes is useful to determine evolutionary patterns and specifically important in the study of genetic disorders. It can hence be used as a flexible tool in the context of studying the specific genetic question at hand.

## Harry Harlow

Marieke Cassia Gartner  
Zoo Atlanta, Atlanta, GA, USA

### Introduction

Harry Frederick Harlow was born on October 31, 1905, in Fairfield, IA, as Harry Israel. He attended Stanford University as a psychology major, working under Lewis Terman, along with Calvin Perry Stone, an animal behaviorist, and Walter Richard Miles, a vision expert. He received his Ph.D. in 1930 and became a professor at the University of Wisconsin-Madison, where he established his Primate Laboratory and did most of his work. In 1970, he moved to the University of Arizona. He was prolific, publishing 325 articles and chapters (Suomi and LeRoy 1982). He is considered highly controversial due to his treatment of the monkeys in his lab, but at the same time as one of the most important psychologists to contribute to the field. His most well-known and similarly controversial doctoral student was Stephen S. Suomi. He died December 6, 1981, in Tucson, AZ, at 76 years of age.

### Scientific Interests

In the beginning of Harlow's career, Behaviorism was the main school of thought in the animal psychology field (see "▶ [Behaviorism](#)").

Behaviorism maintained that one could scientifically study overt behaviors, but nothing else (no cognitive function, no emotions). This was done through the use of conditioning (see "▶ [Classical Conditioning](#)"), as was made famous by Pavlov (see "▶ [Ivan Pavlov](#)"). The belief was that animals were not capable of other functions (such as emotions or cognition), or, if they were, those things were immeasurable. The behaviors that were measured were those that were conditioned to occur – clearly a significant limitation in understanding animals. Harlow broke with this practice and studied learning in rhesus macaques (*Macaca mulatta*) in a different way. He started working with monkeys by accident – the rats that psychologists typically studied had gone from the University of Wisconsin, and he needed to find a different subject. Starting at the zoo, he eventually created a macaque primate lab at the university. Harlow was not interested in the rats or the monkeys for their own sake, but for what they could tell him about humans.

Harlow used the Wisconsin General Testing Apparatus (WGTA), created in his lab by Drs. Paul Settlage and Walter Grether, for macaques (Harlow 1949), in order to understand intellectual organization and personality structure. Harlow showed that monkeys could think abstractly and problem solve. He utilized the object-quality discrimination learning problem, which required the monkey to choose a rewarded object over a neutral object based on varying characteristics and shifting positions in a balanced order; he also compared the results to human children, showing the similarity of the learning curves (Harlow 1949). This was the impetus for many later studies looking at monkey intelligence and learning capacity. This type of experiment also allowed animal psychology to move beyond Behaviorism, and encouraged the comparison of ability in monkeys and human children (Suomi and Leroy 1982). It is thought by some that Harlow's work was heavily influenced by John Bowlby, a founder of attachment theory in humans, and vice versa, both cited one another, and Harlow was able to show what Bowlby had theorized about in terms of the effects of attachment and separation (van der Horst et al. 2008) but could not test

because of the ethics standards of testing on humans that are absent for monkeys.

To understand what parts of the brain corresponded with different learning and memory tasks, Harlow also carried out lesion studies to assess the macaque brain and to see which parts were associated with learning (e.g., Harlow and Dagnon 1943; Harlow 1949, 1952). This was widely accepted at the time (and currently), because it was/is not allowed to experiment on human subjects. Experimenting on animals, then, was considered the next best thing to advance science. These studies showed, for example, that animals with bilateral frontal lesions were not affected in visual discrimination tests, but those with posterior lesions were. The opposite results were found for tests of delayed response (although without complete loss of function). Neither group performed as well as unoperated monkeys in a complex learning test (Harlow 1950; Harlow et al. 1952). These results were considered important in that they outlined that different parts of the brain are responsible for different functions, although not with exclusivity.

## Theory of Affection

In order to study development and motivation, Harlow established a breeding colony of macaques in the 1950s. As was typically the practice at the time, Harlow kept the macaques in isolation, in what was thought to be best to protect from the spread of such diseases as tuberculosis (van der Horst et al. 2008). In doing so, he noticed that the macaques were not behaving “normally” – that is, they displayed non-nutritional sucking behaviors, stereotypies, hostility, and inability to form social relationships (Harlow et al. 1965). Harlow hypothesized that basic needs were not the only motivation for monkeys – that affection, or love, was a necessary component for bonding. He showed this with his infamous cloth mother experiments (Harlow and Zimmermann 1959), where baby monkeys were observed to prefer a cloth “surrogate” mother (a contraption made with wire and covered with cloth) without food to a wire surrogate with food (variations on this

were carried out in which the cloth surrogate was considered preferable to other stimuli than food – to a heating pad, for example). He came to the conclusion that bonding was a result of contact rather than being fed (Harlow 1958), which he called “contact comfort” (Harlow and Zimmermann 1959). This is considered one of Harlow’s breakthroughs, as the theory at the time supposed that human babies need only nutrition to survive normally. Harlow’s experiments changed the thinking in that area. In addition, Harlow subjected the infants to fright-inducing stimuli, to assess their response to the surrogate mothers (Harlow and Zimmermann 1959). When the infants were subjected to the frightening stimulus, they would run to the cloth surrogate – after rubbing their bodies on hers, they would then lose their fear of the stimulus, visually exploring it, and some actually approaching it. Harlow hypothesized that nursing, then, was not only a nutritional resource but meant to increase contact between mother and infant, so that the infant could easily obtain contact comfort (Harlow and Zimmermann 1959).

Following these experiments, Harlow’s interest in attachment and separation grew, especially as it pertained to development. To understand these mechanisms, he conducted increasingly extreme experiments. In what many would consider one of his most egregious experiments, he subjected infants to 2-year long isolation periods in small cages in order to record how it would affect their behavior (Harlow et al. 1965). He found, unsurprisingly, that it did, in very adverse ways, with the monkeys showing extreme abnormal behaviors, including severely impairing social, sexual, maternal, and aggressive behaviors. He claimed that 6-month total isolation was “so devastating and debilitating” (Harlow et al. 1965), and expected that a longer period of isolation could not possibly be worse. Unfortunately, he tested that theory, and proved himself wrong. While some consider all of Harlow’s work unacceptable, even those who support his strict adherence to the scientific method and the information he uncovered might at this point wonder exactly what useful information these extreme experiments revealed, and at what cost.

Next, Harlow tried to reverse the effects of the social isolation to which he subjected the monkeys, with varying results (Harlow and Suomi 1971). Some mothers showed appropriate maternal behavior with prolonged exposure to an infant, but nothing more, while infants exposed to untested peers had limited recovery. Infants exposed only to surrogate mothers were able to interact at a low level among themselves, but not with others. When Harlow exposed 6-month old isolated monkeys to 3-month old untested infants, however, the 6-month olds were able to recover normal behavior completely, at least as tested by the experiments available in Harlow's lab (Harlow and Suomi 1971).

What Harlow found changed how psychologists thought about motivation and development not only in monkeys but in humans as well (Suomi and Leroy 1982; although see Mason 1968, for another opinion). They revealed how important social interaction is for social species, especially at the developmental level, but also for learning (Harlow et al. 1965) and maternal behavior (Seay et al. 1964). Notably, Harlow used the term "love," which was considered unorthodox in referring to animals' feelings both at that time and currently.

In later years, Harlow tried to assess depression in macaques that was instigated by the social isolation that he imposed on them. His aim was to find a parallel with human depression (Harlow and Suomi 1971). In order to do so, he aimed to meet three conditions set by McKinney and Bunney (1969): external expressions and behaviors of depressed humans and depressed monkeys must be parallel; etiological conditions must be similar, such as heredity, anxiety, or social loss; and that any therapeutic interventions that work successfully for humans should also, therefore, work for the monkeys. Harlow concluded that he could induce depression similar to that found in humans in monkeys via separation. He also attempted to reverse it, with varying results (Harlow and Suomi 1971; Suomi et al. 1976). Harlow claimed he had both acted as a sadist in trying to create abnormal behavior, and as a psychiatrist in trying to rehabilitate the depressed monkeys (Harlow et al. 1971).

## Awards and Honors

Harlow was awarded the Howard Crosby Warren Medal in 1956, the Distinguished Psychologist Award from the American Psychological Association in 1960, the National Medal of Science in 1967, the Gold Medal from the American Psychological Foundation in 1973, the Von Gieson Award from the New York State Psychiatric Institute, and the International Award from the Kittay Scientific Foundation. He held many positions of honor, including as Carnegie Fellow of Anthropology at Columbia from 1939 to 1940, the George Cary Comstock Research Professor of Psychology from 1944 to 1974, President of the Midwestern Psychological Association from 1947 to 1948, President of Division of Experimental Psychology at the American Psychological Association from 1950 to 1951, Head of Human Resources Research branch of the Department of the Army from 1950 to 1952, Head of the Division of Anthropology and Psychology of the National Research Council from 1952 to 1955, Consultant to the Army Scientific Advisory Panel, President of the American Psychological Association from 1958 to 1959, Director of the Regional Primate Research Center from 1961 to 1971, and President of the Division of Comparative & Physiological Psychology at the American Psychological Association from 1964 to 1965.

## Controversy

Harlow is considered a controversial figure in psychology today – many admire him and believe he advanced the field of animal psychology in a way no one else did, while others consider him to be needlessly cruel and capricious in his social isolation experiments (Blum 2002). He has been credited with igniting the animal rights movement (Blum 2002). In addition, his blatantly sexist commentary (e.g., Tavis 1973) is viewed by some to be a sign of the times or as his intentionally mocking personality, and by others as indicative of his sexism.

## Healthy Mate Hypothesis

Monika Siekelova  
University of Cambridge, Cambridge, UK

## Synonyms

[Good genes hypothesis](#)

## Definition

The healthy mate hypothesis states that mate choice is based on secondary sexual characteristics that act as a proxy for assessing the potential mate’s overall health and parasite resistance.

## Introduction

Sexual selection works on the premise that, out of a pool of potential mates, only few succeed to mate. Usually, the member of the sex that invests more into reproduction undergoes some form of assessment of the potential mate in order to maximize their reproductive success, which in turn

creates a selection pressure. Maybe one of the most famous examples of sexual selection is that of the peacock and the peahen. The long, elaborate tail of the peacock has played a role in Darwin's development of sexual selection theory (Darwin 1859, 1871). Darwin could not explain this attribute with natural selection, as the extravagant tails of peacocks do not appear to be a form of adaptation for survival. Sexual selection, however, provides an explanation to the persistence of such an extravagant male morphological trait (Darwin 1871). Although the trait has a negative impact on the peacocks, due to the increased risk of predation and decreased agility, they remain in the population due to the increased reproductive success of those males due to female choice (Andersson and Simmons 2006). This type of selection arises from mate choice and mate assessment. When an individual's reproductive output is limited or costly, assessing potential mates and basing the choice on that assessment results in many benefits (Breed and Moore 2015). Although sexual selection is widely accepted as the selection force on traits that cannot be explained by natural selection, the mate choice that drives sexual selection can be explained by various hypotheses and models, including the healthy mate hypothesis. The healthy mate hypothesis suggests that females choose healthy mates for the direct benefit of avoiding disease transmission or for indirect benefit of passing on their "good genes" for parasite resistance.

### **Mate Choice and the Benefits of Mate Assessment**

Animals can base their choice of a mate on several criteria, which can be divided into two main categories: those that provide direct benefit (such as good territory, parental investment, or nutritional gifts received during courtship) and indirect benefits such as the genetic quality of the potential mate. However, it is important to note that these are not mutually exclusive and a mate choice can be made based on several of these in the same population (Breed and Moore 2015).

### **Direct Benefits**

Many animals choose their mate on the direct benefits they gain from the mating. These are in the form of nongenetic benefits that have a positive impact on the offspring production or survivorship. These include females choosing mates based on the quality of their paternal care (Davies 1992), the quality of nuptial gifts presented during courtship (Thornhill and Alcock 1983), or access to better territories (Alatalo et al. 1986; Candolin 2003).

### **Indirect Benefits**

Female choice based on indirect benefits is harder to detect as the benefits are experienced by the next generation as either increased survivorship ("good genes") or higher mating success ("sexy sons") (Andersson 1994).

### **Sexy Sons**

The "sexy sons" model suggests that the only benefit of the female's choice of a mate is the increased reproductive success of her sons (Lande 1981). This model explains the exaggeration of secondary sexual characteristics, such as those of the peacock tails discussed earlier, through a consistent preference for a certain trait which, over generations, produces an extreme form. For example, if females persistently choose to mate with males that are brightly colored, then brightly colored males will produce more offspring. Subsequently the male offspring will be more brightly colored and therefore sexually attractive, and the female offspring will inherit the preference for the bright colors (Fisher 1930). Although the characteristic can be regulated to a certain point by natural selection, this form of selection can easily result in an exaggeration of the trait that is being selected (Fisher 1930). This form of selection is referred to as runaway sexual selection and explains how deleterious characteristics could arise and persist in a population. The consistent selection for a specific trait will then decrease the genetic variation in the next population, as sexy sons have higher reproductive success, and this results in

the trait quickly becoming fixed in the population (Rowe and Houle 1996).

## Good Genes

The “good genes” model, on the other hand, suggests that females use proxies, such as secondary sexual characteristics or bright plumage, to assess the quality of the genes of the potential mate. In order to demonstrate the benefits of females choosing a mate based on their “good genes,” there are several criteria that need to be met. These include:

1. The male survivorship needs to genetically vary in a given population.
2. The behavior or ornaments the females use to assess the quality of their mates should provide accurate information on the survival ability.
3. Females must base their choice on these attributes.
4. There is a direct benefit to the offspring survival or reproductive success based on their mother’s choice (Andersson 1994).

## Healthy Mate Hypothesis

The healthy mate hypothesis is a subcategory of the “good genes” model. It states that mate choice is based on secondary sexual characteristics, which act as a proxy for assessing the potential mate’s overall health and parasite resistance. The healthy mate hypothesis can be further subdivided into two categories based on the type of benefits: indirect benefits (Hamilton-Zuk hypothesis) and direct benefits (parasite avoidance hypothesis) gained by mate choice (Borgia 1986; Hamilton and Zuk 1982).

### Hamilton-Zuk Hypothesis

The Hamilton-Zuk hypothesis suggests that genetic variation in the population can be maintained by the interaction of mate choice and the negative impact of parasitic load on secondary sexual traits (Hamilton and Zuk 1982). Hamilton and Zuk suggested that females make their choice

based on the perceived health of the potential mate and suggest that males that have higher parasite resistance will have more exaggerated secondary sexual characters, which in turn facilitates female choice (Hamilton and Zuk 1982). This means that the male trait and female preference never reaches an equilibrium due to the evolutionary arms race between the parasite and their hosts (Møller and Saino 1994). Genes for the parasite resistance change in response to the parasites’ adaptations, and, therefore, the fittest genotype changes from generation to generation. This explains the variation in male traits associated with resistance. Similarly, to the “good genes” model, in order for the Hamilton-Zuk hypothesis to work, there are several assumptions that need to be met. These include:

1. Host fitness need to decrease with increased parasitic infection.
2. Ornament condition needs to decrease with increased parasite burden.
3. Female choice must favor the most ornamented males.
4. Female choice must favor the least parasitized males.

### Parasite Avoidance Hypothesis

An alternative to the Hamilton-Zuk hypothesis is the parasite avoidance hypothesis which suggests that females preferentially choose males that are healthy due to the direct benefit of avoiding disease and parasite transmission (Borgia 1986; Hamilton and Zuk 1982). This hypothesis is especially relevant in species with directly transmittable diseases and parasites, and, unlike the Hamilton-Zuk hypothesis, it does not require all the assumptions to be met. The parasite avoidance hypothesis does not predict a negative impact of parasites on traits nor that females assess the health of a potential mate based on those traits (Møller 1990; Zuk 1992). Few studies, including a study on satin bowerbirds, show that females avoid mating with parasite-infected males and they hypothesize that this can help them avoid novel pathogens that could be transmitted by those parasites (Borgia and Collis 1989).

## Conclusion

Mate choice is the basis of sexual selection. Although there are numerous models and hypotheses described in the literature on mate choice and the benefits of assessing a potential mate, they are not inherently exclusive. Mate choice does not have to strictly be about direct or indirect benefits as mate choice is often based on several criteria. Even within indirect benefits, whether a choice has been based on “sexy sons” or “good genes” model is often hard to distinguish. There appears to be a dichotomy between these two models in the literature, but they are not mutually exclusive, and both should be carefully considered (Kirkpatrick and Ryan 1991). The healthy mate hypothesis has been of great interest since Hamilton and Zuk proposed it in 1982 and remains so to this day. However, there is still more to investigate as the issue of mate choice is far more complex than a single hypothesis can encapsulate.

## Helping Behavior

Rodrigo Landabur<sup>1</sup>, Mario A. Laborda<sup>2</sup>, Gonzalo Miguez<sup>2</sup> and Juan E. Wilson<sup>1</sup>

<sup>1</sup>Department of Psychology, Faculty of Social Sciences, University of Chile, Santiago, Chile

<sup>2</sup>Departamento de Psicología, Facultad de Ciencias Sociales, Universidad de Chile, Santiago, Chile

*Helping behavior* is any action performed by an individual that benefits other individual/s. Helping does not imply a pro-social motivation or unselfish intent to alleviate others' needs or increase their welfare as an end in itself. In fact, there might be difficulties to identify and evaluate those motivations, especially in nonhuman animals, in which even the mere existence of them is being discussed.

Explanations of helping behavior can be organized in terms of proximate and ultimate causes. Proximate causes point to how helping behavior was acquired and occurs in a specific context. They are the mechanisms directly implicated in the development and display of helping, such as the learning history and the cognitive, emotional, and physiological reactions in a specific situation.

Ultimate causes are explanations of why helping behavior has been selected throughout evolutionary history. They refer to the functional utility of helping behaviors for the survival of the helper and the reproduction of his/her genes. This entry is focused on those ultimate causes.

## Types of Helping Behavior

It is possible to distinguish types of helping behavior depending on the costs and benefits to the helper.

### Altruism

Altruistic helping is defined as the aid to another individual with a cost for the helper. At first glance, it may be hard to understand how a costly behavior such as this may have persisted through evolution, since natural selection tends to eliminate any trait that reduces the individual relative fitness (i.e., one's reproductive success relative to that of other members of the population). Thus, for altruism to remain across generations, it should increase the propagation of the helpers' genes. Charles Darwin realized that this is the case when altruistic helping is directed toward an individual genetically related to the helper (Darwin 1859). This idea is at the core of William D. Hamilton's *kin selection theory*.

Hamilton (1964), observing the behavior of insect colonies (bees, ants and wasps), proposed that kin selection involves indirect fitness (i.e., copies of one's genes in other bodies). He created an equation that predicts altruistic behaviors are more likely to be favored by natural selection when the reproduction benefits for the recipient, weighted by the degree of relatedness between helper and recipient, are greater than the reproduction costs for the helper.

Kin selection can explain helping behavior toward genetically related individuals, but why is helping sometimes oriented toward nonkin as well? One answer to this question was offered by the concept of *reciprocal altruism* (Trivers 1971). In reciprocal altruism an individual aids other individuals because chances are they will respond

in kind, benefiting the helper at some point in the future, thereby increasing the likelihood of the helper's survival and hence the selection of this altruistic trait. Reciprocal altruism requires conditions that increase the frequency of interactions between the helper and the recipient: (a) long life span of both individuals (which provides more opportunities for them to interact with each other over time), (b) low dispersal rate (an individual interacts more often with the same others), and (c) interdependence of members (they need each other so they tend to stay closer to one another, increasing their interactions). Reciprocal altruism has been documented in humans and nonhuman individuals, in laboratory and field studies in the former case, and mainly in field studies in the latter. Although reciprocal altruism has been usually used to account for altruistic behavior toward unrelated individuals, it can also explain providing help to relatives (Trivers 1971). For instance, in species with parental care, helping offspring could be selected by evolution because they tend to reciprocate the help to the parents. In sum, kin selection and reciprocal altruism could both explain altruistic behavior toward relatives.

In humans, reciprocal altruism is seen in several different situations, as in the helping exchanges between members of the same neighborhood, and the games about sharing and allocating resources to others which are played in controlled, experimental contexts. Reciprocal altruism is facilitated in humans due to their cognitive ability to remember past interactions with the recipient and to project who is likely to return the help in the future.

For nonhumans species, reciprocal altruism has been observed in fishes and shrimps cleaning other species (Feder 1966). They get ectoparasites from the gills or mouth of host individuals and ingest them. The reciprocity of the hosts involves refraining themselves from eating the cleaners, along with protecting them from other predators.

Fishes and shrimps would meet the three conditions for reciprocal altruism reviewed. However, Trivers (1971) additionally discussed the relevance of detecting "cheaters" (individuals who do not return the favors), who act against the development of reciprocal altruism. This detection mechanism can be found in humans,

but it is hard to prove in nonhuman species. Detecting cheaters requires the capacity of individual recognition, which can be observed in mammals (e.g., dogs), and birds, such as the *Wilsonia citrina* or the *King penguins* (Tibbetts and Dale 2007). Nevertheless, there is not consistent evidence about cheater detection in nonhumans. Thus, this is one of the main challenges for future studies.

An extreme case of altruism is rescue behavior: rescuers risk their lives when helping others. Evidence for this type of altruistic behavior has been found in field studies conducted on dolphins, monkeys, ants, and humans (e.g., Taylor et al. 2013). Ants rescue conspecifics only, while humans extend this behavior toward members of other species as well. Monkeys and dolphins rescue conspecifics, but there is not yet evidence that they do so with members of other species. The rescue behavior toward conspecifics could be explained by kin selection (considering the shared genes between helper and recipients) or reciprocal altruism (depending on the conditions reviewed above).

## Cooperation

Cooperation occurs when two or more animals act together in the same activity, which benefits them. In this case each helper is also a recipient. Although some individuals in the group may benefit less than others (e.g., getting a smaller piece of the prey they were all hunting down together), they would still get rewarded by obtaining something they could hardly achieve by working individually. Thus, this type of helping behavior promotes the survival of all the helpers and therefore the transmission of their cooperative genes to the next generation. Cooperation has been observed in numerous species in laboratory and field research, mainly in contexts where there is a common threat (a predator, for example) or when individuals can benefit by acting together: ants work in groups to transport pieces of food, lions make the same to protect their group, birds have cooperative breeding systems, and humans coordinate their actions to create economic goods (see Rubenstein and Abbot 2017).

In nonhuman species cooperation is mainly seen among individuals who have lived together

for a long time. An interesting exception is the thorn-tailed Rayadito (*Aphrastura spinicauda*; Furnariidae), a nontropical suboscine species that lives in the south of Chile and Argentina. Although they maintain short-time ties between them, they show coordination to defend their territory (Ippi et al. 2017).

In humans, cooperation is frequently observed between acquainted and unacquainted individuals, who work together to obtain material resources (e.g., food or money) as well as more abstract resources (e.g., social status), which requires more cognitive development.

In sum, according to ultimate causes of helping behavior, altruistic and cooperative traits have been naturally selected for the reasons reviewed. An alternative evolutionary explanation for altruism postulates its selection at a group level.

## Altruism and Group Level Selection

*Multilevel selection theory* claims that traits can be selected at different levels, from genes to groups (Wilson and Sober 1994). According to this theory, altruism is not selected at the within-group level because altruistic individuals have a relative fitness disadvantage because they increase the fitness of selfish members at a cost to themselves and without receiving help in return. On the other hand, altruistic groups do beat selfish groups. Groups with a higher proportion of altruistic individuals have stronger functional organizations than those composed mainly of selfish individuals, resulting, for instance, in their more solid system of feeding and defense against external threats which, in turn, allows them to have more offspring. Therefore, altruistic traits are selected at the between-groups level because they give altruistic groups a reproductive advantage over the selfish groups. In sum, according to this theory, altruism evolves whenever between-group selection prevails over within-group selection.

An extreme example of selection between groups is eusocial species such as some types of ants, wasps, termites, and bees. They are composed of sterile and nonsterile members. The former cannot reproduce themselves but benefit the

colony, for example, by taking care of the young ones, which is an essential function to maintain the colony survival (Wilson and Hölldobler 2005).

## Conclusion

According to ultimate causes of helping, it is possible to differentiate between altruistic and cooperative types depending on the costs and benefits to the helper. Altruism toward a related individual could be explained by either kin selection or reciprocal altruism, while helping toward nonkin by the latter theory only. Additionally, it is necessary more research in nonhumans species about the “cheater” detection system required for reciprocal altruism. Likewise, more studies are needed on cooperation in short-time relationships.

According to multilevel selection theory, there are different levels of natural selection of traits, from genes to groups. In terms of survival and reproduction rates, groups composed of many altruistic individuals have an advantage over those integrated by few altruistic individuals; therefore, those traits will evolve if between-group selection is stronger than within-group selection.

It is debated whether kin and multilevel selection theories are different approaches or the former is a special case of the latter: altruistic behaviors toward members in a group with high genetic similarity benefit both the kin (i.e., kin selection) and the group over others (i.e., group selection). Another debate is whether there is genuine altruism in evolutionary theories or it is only selfishness in disguise. For multilevel selection theory, altruistic behavior involves a cost for the helper and a benefit for the group, but according to kin selection and reciprocal altruism theories, altruism would be just apparent because it is driven by indirect fitness and a returned help in the future, respectively, so it is self-beneficial.

## Hematophagy

R. A. Boulton  
College of Life and Environmental Sciences,  
University of Exeter, Penryn Campus, Cornwall,  
UK

### Definition

Feeding on blood of another living organism.

## What Is Hematophagy?

Hematophagy (also known as sanguinivory) is the practice by some animals of feeding on the blood of other vertebrate animals (or in some cases the hemolymph of invertebrate animals). The first known hematophages (blood feeders) were the protomosquitoes, of which there is fossil evidence from 220 million years ago (Schutt 2008). Today there are thousands of species that feed on the blood of other animals (their hosts), both obligately and facultatively. Obligate hematophagy has evolved multiple times in the invertebrates, including the insects and arachnids (15,000 blood-feeding species representing at least six evolutionary events; Mans et al. 2002; Lehane 2005), leeches (Hirudinea; Schutt 2008), and nematode worms (Munn and Munn 2002). Hematophagy is also seen in some vertebrates, including the infamous vampire bats (three species in the *Desmodontinae*; Schutt 2008) and fish (such as the lampreys and candiru; Schutt 2008). Obligate blood feeding is not known in other classes of vertebrates, but some bird species feed on blood facultatively. This includes one of Darwin's finches, *Geospiza septentrionalis*, the vampire finch, a subspecies of the sharp-beaked ground finch that supplements its diet of seeds and nectar with the blood of the blue-footed booby (Grant et al. 2000).

## Adaptations for Hematophagy

There are several constraints that hematophagous organisms need to overcome to survive on a diet of blood. Blood feeders need to (i) find a host on which to feed, (ii) attach to the host in order to feed, (iii) access the blood of their host, and (iv) digest the blood meal. There are only a certain number of ways that hematophages can achieve these tasks, which has led to some striking examples of convergent evolution across distantly related taxa.

### Locating a Host

Finding a host can be a complex challenge for hematophages. Some species have overcome this

issue by forming permanent associations with their hosts as ecto- or endoparasites. This includes lice, parasitic polychaete bugs, and nematodes (Lehane 2005; Schutt 2008). The bat flies (Diptera: Nycteribiidae and Streblidae) have developed an obligate association with specific species of bats, feeding exclusively on the blood of their host, some even embedding into the skin and existing as endoparasites (ter Hofstede et al. 2004; Dick and Patterson 2006; McAlister 2017). Many bat fly species, particularly the Nycteribiidae, no longer have functional wings as they rely entirely on their bat hosts for dispersal (phoresy) to find new hosts in communal roosts (Lehane 2005; McAlister 2017). Another group of blood-feeding insects, the bed bugs (Hemiptera: Cimicidae), have also lost functional wings after they came to rely on their mobile hosts for dispersal (Cummings 1949; Lehane 2005).

There are many species that are not permanently attached to their hosts, however, and thus these species must find hosts on which to feed. The complex nature of host-finding behavior is apparent when we look at the diversity of antennal receptors across the insects. Species with more constant associations with their hosts (such as the lice) have far fewer antennal receptor types than those needing to seek out hosts on which to feed (Lehane 2005). The function of these receptors relates to the complexity and diversity of the cues these organisms use to find their hosts. Most species use a combination of visual, olfactory, and temperature cues to find their hosts, and the range at which species are searching influences which cue combinations are the most informative. Visual and volatile olfactory cues provide information to hematophages that are engaged in appetitive searching at longer distances, but after becoming attracted to these cues, many species use heat, humidity, and olfactory cues at a closer range (Lehane 2005; Hinkle et al. 1991). CO<sub>2</sub> emitted from a respiring host is perhaps the most commonly used cue across hematophagous species, but it is typically used in combination with other host kairomones that permit the expression of more specific host preferences, the evolution of host specificity (Lehane 2005), and even the speciation through host-race formation (Balvin et al. 2012).

## Attaching to a Host

In order to feed on blood, hematophagous species must attach to their hosts unnoticed for long enough to attain a sufficient volume of blood to survive and reproduce. There are a range of physiological adaptations displayed by hematophages to attack and evade their hosts, and many of these show striking convergence.

For instance, the use of analgesic components in the saliva, ctenidia (or combs), hooks, suckers, and denticles that allow attachment to the pelage and skin of the host and flattening of the body (anteriorly and dorsoventrally) to avoid being groomed off the host and to permit easy movement in feathers and fur (Lehane 2005; Schutt 2008). The behavior of hematophages is also critical to avoiding host detection, for instance, many species congregate on areas of the body that their hosts cannot access, such as in the nostrils (like some leeches; Lehane 2005). The vampire bats appear to have developed a particularly novel solution to pacify their hosts and allow them to feed – when feeding on domestic hens, they snuggle into the brood patch or jump on the female's back. These behaviors are thought to mimic the action of brooding chicks or mating cockerels, pacifying the hen, and allowing the vampire bat to feed on female hosts undisturbed (these strategies do not work on male hosts; Schutt 2008).

## Accessing Blood

Once a host has been located and latched on to, a hematophage must get access to the blood in the body of its host. In some cases blood feeders (usually facultative hematophages) take advantage of open wounds or lesions on their hosts (Schutt 2008). More commonly, however, the hematophage possesses adaptations that allow it to pierce the host integument to access a blood meal.

There are several ways to access the blood, most of which have involved modification of the mouthparts; these can be broadly categorized as piercing/sucking or ripping/tearing, which allow for either true bloodsucking or pool feeding,

respectively. Bloodsuckers such as the nematoceran Diptera (mosquitoes and midges), the Hemiptera, and the vampire moth use proboscis-like structures to pierce the skin and strong pharyngeal muscles to create a negative pressure gradient that moves the blood from its host into the digestive system (Lehane 2005). Pool feeders include most species of blood-feeding brachyceran flies and vampire bats; they cut through the skin of the host and lap or suck up the blood from the resulting wound (Schutt 2008; Lehane 2005). The structure and function of the adaptations a species possesses to obtain a blood meal can provide information about how hematophagy has evolved. For instance, the strong lancetlike proboscis of the vampire moth (*Calyptra eustrigata*, Lepidoptera: Noctuidae) has most likely evolved from an ancestor with mouthparts adapted to piercing fruits (Lehane 2005) and the high-pressure feeding strategy of the hemipteran blood feeders likely evolved from a sapsucking ancestral state. The cutting/scraping mouthparts of the blood-feeding muscid flies may have evolved from a more generalist ancestor that fed opportunistically on scabs and open wounds (Lehane 2005). Regardless of how blood is accessed, one feature common to the majority of blood-feeding species is the presence of anticoagulant components in the saliva. These components are applied to the host wound to prevent clotting and allow uninterrupted feeding for long periods of time (Lehane 2005; Schutt 2008).

## Digesting Blood

The challenges associated with a hematophagous lifestyle extend past obtaining a blood meal, particularly for species that rely solely on blood for nutrition. Although blood is a high-value protein resource that often represents an unoccupied niche, there are a number of challenges inherent in digesting and sequestering it. Blood is comprised of protein and water, which means that the energy it contains cannot always be easily stored in the long term. This means that blood meals need to be large, but the high water content results in many blood feeders becoming engorged

after feeding, with leeches and ticks being obvious examples (Schutt 2008). The weight and size gain associated with blood feeding is risky, and recently fed hematophages are vulnerable to predation after feeding. The costs of digestion and processing of the blood shape the behavioral ecology of obligate hematophages. This is perhaps most apparent in the vampire bat, which has novel adaptations to deal with both digestion (blood moves into the intestine before the stomach, which allows water to be excreted more rapidly; Wimsatt and Geurriere 1962) and locomotion (crawling along the ground and “catapult” jumps to initiate flight after a large blood meal; Altenbach 1979). The constraints on energy storage also mean that vampire bats cannot survive for long without a blood meal. This, combined with their social habits, is thought to have contributed to their altruistic behavior, which is a key example of how altruism can be beneficial through reciprocity, not only kin selection (Wilkinson 1984; Schutt 2008).

In large amounts blood can be poisonous due to iron toxicity, and excess protein can be damaging, and so hematophagous species need to neutralize these risks. In addition to potential toxicity, blood also lacks many key nutrients, for instance, vitamin B (Kikuchi 2009). Because of the low nutritional content of blood, most hematophagous species have associated endosymbiont bacteria that act mutualistically to provide the lacking dietary components (Kikuchi 2009). In the many obligate hematophagous insects, these bacteria are housed in the mycetome, which is an intestinal organ that contains symbionts that aid digestion and nutrition (Lehane 2005).

## Significance and Summary

Hematophagy is found in a wide phylogenetic range of taxa and demonstrates the power of natural selection in overcoming seemingly overwhelming issues in terms of locating, attaching to, feeding on, and digesting the blood of their hosts. There is much to be learned from hematophagous species in terms of their behavioral and physiological adaptations, but many of these species are also

important from an applied perspective. When hematophagous species feed on the blood of humans, and the domestic animals associated with them, they can threaten human health and economy by transmitting a range of diseases. Many hematophagous species vector some of the world's deadliest and most debilitating diseases, such as rabies (the vampire bat), typhus (mites and fleas), plague (fleas), and Lyme disease (deer ticks). The female *Anopheles* mosquito is perhaps the most deadly example, responsible for transmitting all four species of malarial plasmodia that affect humans, and causing millions of deaths per year (Lehane 2005). Other insects, such as the tsetse fly and various assassin bug species, spread trypanosomes, the pathogenic protozoa that cause sleeping sickness and Chagas disease in humans and nagana in cattle (Lehane 2005).

Despite the considerable damage to human and animal health that hematophages can impose, they have also contributed significantly to the improvement of human health. Anticoagulants and analgesics found in the saliva of hematophagous species such as the leech and the vampire bat have led to enormously important medical developments, such as in the treatment of strokes and chronic pain. Leeches are still used in the medical sciences today; treatment with leeches prior to tissue reattachment prevents venous congestion and increases the success of the procedure (Conforti et al. 2002). Much remains to be discovered about the hematophages (particularly those that have not shown to be of medical or economic importance), and the adaptations that allow these species to find and subsist on blood will no doubt continue to contribute to our understanding of evolution as well as lead to many more critical medical advances.

## Synonyms

[Behavioral lateralization](#); [Brain/cerebral/hemispheric asymmetry](#); [Hemispheric dominance](#)

## Definition

Hemispheric specialization refers to the differential role of the left or right brain side in processing a specific neuronal task or behavior. One hemisphere might be predisposed to adopt a function because of specific structural and/or computational characteristics. This dominance can be expressed in enhanced sensory performances, decision-making, and/or superior motor skills.

## Introduction

Bilaterian animals are characterized by a basically symmetrical body plan including a nervous

system typically ending with brain-like structures at the front. Each half of the brain processes information from one environmental half field and controls one body side. In several cases, however, one hemisphere dominates a specific function (hemispheric specialization). Consequently, this hemisphere takes control in organizing and controlling motor responses that become visible as asymmetrical behavior. Humans, for instance, preferentially use one hand (typically the right one) for writing or tool use reflecting dominance of the contralateral (left) hemisphere for fine-tuned motor control (handedness). Humans also have a preferred leg for kicking a ball and a favored eye for looking through a camera lens and open their mouth asymmetrically while speaking. The right side opens more widely due to left-hemispheric control of articulation. This asymmetry is related to a general left-hemispheric dominance for speech processing. Consequently, left-hemispheric strokes entail loss of speech since the right brain side cannot efficiently compensate deficits. The careful description of patients with left-hemispheric language impairments by Paul Broca (1865) was actually the dawn of asymmetry research (Ocklenburg and Güntürkün 2017). In contrast to what this example indicates, hemispheric specialization does not necessarily mean that the other hemisphere is not able to conduct a function at all or that it does not participate in task performance. Concerning speech processing, the right hemisphere, for instance, is specialized to analyze rhythm and word melody (prosody), which are necessary to understand the emotional content or irony of a speech (Ocklenburg and Güntürkün 2017).

Hemispheric asymmetries have been originally regarded as an exclusively human trait evolved within the scope of tool use abilities, upright body posture, or generally higher cognitive skills. The scientific community therefore assumed that brain lateralization is based on an asymmetrical cortical forebrain organization (Ocklenburg and Güntürkün 2017). Recent research, however, provides more and more examples of lateralized brain processes in other vertebrates and even in invertebrate species (Concha et al. 2012; Frasnelli

2013; Rogers et al. 2013; Rogers and Vallortigara 2017; Vallortigara and Rogers 2005). Preferential limb use for object manipulation is shown for primates, monkeys, lemurs, mice, bats, wallabies, parrots, or toads (Fig. 1a), and even invertebrates preferentially use one of their limbs including locusts, spiders, or octopuses (Frasnelli 2013; Niven and Frasnelli 2018). Motor asymmetries can also be expressed as positional or turning biases. Individuals may show consistent side preference when avoiding an obstacle, exploring the natural or laboratory test (maze) environment, or display a consistent turning bias during escape responses (as shown, e.g., ants, bumblebees, chicks, cuttlefish, fish, octopuses, or rodents).

Apart from motor asymmetries, individuals can display perceptual asymmetries. This means they preferentially use one of their eyes, ears, or olfactory organs when exploring the environment. Perceptual dominances are, however, rarely based on peculiarities of the sense organs themselves. They mostly reflect specializations of the correspondent hemisphere. In this sense, turning bias or positional asymmetries can be indicative for hemispheric specialization since this behavior brings the side in focus, which is specialized to analyze the currently

relevant stimuli. In a variety of mammalian species, for instance, the right hemisphere controls social interactions. Accordingly, these species display a preference to keep a social partner on the left side (Giljov et al. 2018).

These first examples indicate the widespread distribution of cerebral lateralization in the animal kingdom. Accordingly, the term hemispheric specialization does not only comprise asymmetries of (cortical) forebrain structures but refers in the following to the functional dominance of one brain side independent from the specific neuronal organization of a species.

## Hemispheric Specialization Pattern

In vertebrates, several aspects of lateralization can be traced back to a complementarily organized behavioral pattern. The left hemisphere plays a dominant role in routine (especially feeding) behaviors including foraging, discrimination of food objects, or prey catching. In contrast, the right hemisphere controls emergency responses and is therefore in charge of novelty or predator detection and avoidance behavior (Fig. 2; Vallortigara and Rogers 2005). This

**Hemispheric Specialization, Fig. 1** Examples of lateralized behavior: (a) orangutan fishing for food with the left hand using a bow indicating that this individual is a left-hander; in contrast to chimpanzees and bonobos, which display population-level right-handedness, orangutans as well as gorillas display individual-level handedness

(Hopkins 2006). (b) A pigeon pecking for symmetrically scattered peas thereby preferentially orienting to the left hemifield. This so-called cancellation task indicates functional dominance of the right hemisphere controlling visuospatial attention (Diekamp et al. 2005)

**Hemispheric Specialization, Fig. 2** Overview of typical lateralization pattern in vertebrates

dichotomous lateralization pattern might be related to an ancient pattern of lateralization that is eventually linked to approach and avoidance behavior (Lippolis et al. 2009). Even invertebrates like the cuttlefish are more likely to favor the left visual field to scan for potential predators (avoidance) and the right visual field for prey attack (approach; Schnell et al. 2016).

Apart from these general patterns, specific functions are lateralized in vertebrates. Different mammalian species including chimpanzees, sea lions, or dogs show dominance of the left hemisphere for conspecific vocalization, while the right hemisphere controls visuospatial attention (Fig. 1b) or face recognition. The direction of limb preferences varies on the other hand profoundly between different species (Ocklenburg and Güntürkün 2017).

Dominances for specific functions are related to hemispheric-specific differences in preferential processing styles (Fig. 2). Different models suggest that the left hemisphere prefers a serial processing style relying on local or high-frequency

aspects of stimuli, while the right hemisphere favors parallel or configural processing, encoding global or low-frequency information. These preferences might predispose one hemisphere to adopt a specific function. The left-hemispheric dominance of conspecific vocalization might be related to its specialization in high-frequency analysis (Ocklenburg and Güntürkün 2017). This means that one hemisphere might dominate a function because of structural and/or physiological advantages, which enable quicker computational processes. In addition, the dominant hemisphere may actively inhibit parallel processing tendencies within the contralateral brain side via commissural systems. In this regard, the action of the corpus callosum in the mammalian brain is deeply discussed (Ocklenburg and Güntürkün 2017).

Allocation of dichotomous analysis strategies enables efficient use of different environmental information depending on the environmental conditions. In the case of spatial orientation, for instance, landmarks provide local feature cues,

while distances represent geometric, global information. Individual can use both types of information whereby the left hemisphere preferentially relies on local cues, while the right hemisphere orients on the basis of geometric cues (Fig. 3).

Hemispheric dominance may vary depending on the environmental context, available cues,

or age, sex, and experience of an individual. Accordingly, many cognitive modules like social or spatial cognition include left- as well as right-hemispheric components, which display differential lateralization pattern in a species-typical manner (Manns and Ströckens 2014; Ocklenburg and Güntürkün 2017).

**Hemispheric Specialization, Fig. 3** How individuals use differential environmental cues for spatial orientation is exemplified in chicks searching for food hidden under sawdust in the center of a square arena. Distances from the wall provide geometric information (indicated by the cross, which is not visible in the real experiment). The orange bar serves as a landmark providing an additional local cue (a). After binocular training, the chicks are confronted with conflict information under different seeing conditions. Since the landmark is shifted to one corner, local and geometric information provide conflicting cues about the localization of food. When seeing with both eyes, chicks search in the center indicating that they rely on geometric

information (b). When using only the left eye (since the right eye is occluded), chicks also concentrate search to the center indicating that the right hemisphere uses geometric information (c). Right-eye-seeing chicks on the contrary search near the landmark indicating that the left hemisphere considers local information (d). A comparison of all results suggests that the right-hemispheric geometric strategy dominates visuospatial orientation (according to Tommasi and Vallortigara 2001). Similar results indicating that the left hemisphere favors a local and the right hemisphere a geometric strategy are reported for food-storing birds (Clayton and Krebs 1994) or pigeons (Bingman and Gagliardo 2006)

## Evolutionary Aspects of Hemispheric Specialization

Cerebral asymmetries seem to be an ancient characteristic of functional brain organization existing since more than 500 million years. Signs of behavioral or morphological asymmetries are reported from fossils of so different extinct and living phyla like Arthropoda, Annelida, Mollusca, Chordata, Conodonts, or Trilobites (Ocklenburg and Güntürkün 2017). A beautiful example are fossilized trilobites, which display 3x more bite marks at their right compared to their left rear. This implicates that their predators tended to attack from the right side or that the trilobites took a skewed position when being attacked (Babcock 1993).

The widespread distribution of cerebral asymmetries suggests profound phylogenetic advantages of a lateralized brain. It is conceivable that the different specialization of the left and right brain hemispheres increases brain efficiency since neuronal division of labor avoids needless double computations and interhemispheric conflicts. A couple of studies support that an increase in lateralization enhances task performances. Chimpanzees with stronger individual handedness are more successful when fishing for termites; in pigeons, enhanced visual asymmetry is correlated with success in discriminating food grains from pebbles (Güntürkün et al. 2000); lateralization enhances numerical skills in the guppy (Dadda et al. 2015); lateralized cuttlefish individuals show faster prey attacking than non-lateralized conspecific (Schnell et al. 2016), and lateralized fruit flies and antlion larvae display enhanced learning or memory abilities (Pascual et al. 2004; Frasnelli 2013; Miler et al. 2017). Moreover, lateralization saves neuronal capacities since an individual can simultaneously process two different tasks. In chickens, for instance, allocation of function with a left-hemispheric dominance for food discrimination and right-hemispheric superiority for predator vigilance enables the birds to efficiently search for food while scanning the environment for potential danger. Similar results were reported for the tropical fish *Girardinus falcatus* or marmoset monkeys (Rogers 2018).

Despite potential advantages, degree and direction of hemispheric asymmetries might vary between individuals of a population. Apart from the absence of any asymmetry, lateralization can be observed at the individual or at the population level (Fig. 3). Lateralization pattern can change during ontogeny and may vary in direction and degree between males and females of a population. Female cats, for instance, are most likely to show right-paw preferences, while male cats more often use their right paws.

In principle, evolutionary advantages of hemispheric specializations should be independent from their direction. Accordingly, some studies prove that strength of lateralization is a predictor of high performance, while direction is not (Ocklenburg and Güntürkün 2017; Rogers 2018). Presence of population-level asymmetries therefore requires specific explanations. Vallortigara and Rogers (2005) suggested that an alignment of behavioral asymmetries in a population arises when individually asymmetrical organisms must coordinate their behavior with that of their conspecifics. Thus, the appearance of asymmetries at population level may have evolved under social selection pressures as an example of an “evolutionary stable strategy.” Thus, population-level asymmetry is more likely when lateralized behavior involves social interactions. This idea is especially proved in insects with social species displaying more lateralized behavior than closely related unsocial ones (Niven and Frasnelli 2018).

## Structural Foundations of Cerebral Asymmetries

Functional lateralizations rely on variances in the organization of the left and right brain side and establish a neuroanatomical basis for any processing advantages. Anatomical asymmetries can be detectable as macroscopic left-right differences, e.g., in the size of gyri and sulci in the mammalian neocortex, or as microscopic differences in intra- and interhemispheric connectivity pattern. In some cases, unique neuronal elements are present on only one side of

the nervous system; in other cases, elements are present on both sides but display left-right differences in number, size, axodendritic complexity, or synaptic organization (Concha et al. 2012).

Depending on the complexity of the nervous system, different kinds of anatomical asymmetries can be present in one species. The fruit fly *Drosophila melanogaster*, for example, possesses an unpaired brain structure (the so-called asymmetrical body (AB)), which is typically present only within the right hemisphere. Mutants with symmetrical organization of AB display impaired retrieval of long-term memory and therefore exemplify the functional relevance of a lateralized brain organization (Pascual et al. 2004). Another example of neurons, which are present on only one brain side, are chemosensory neurons of the nematode *Caenorhabditis elegans*. This worm possesses a limited number of neurons whereby four. The head ganglion of this worm contains a specific cell pair with neuron ASEL located on the left and neuron ASER on the right side. Although anatomically quite similar, the cells differentially respond to different concentrations of the same salt and promote different behavioral reactions. ASEL controls length of forward locomotion, whereas ASER promotes changes in direction (Concha et al. 2012).

In the vertebrate brain, the diencephalic epithalamus, comprising pineal organ and habenulae (Hb), combines different anatomical types of asymmetry. The pineal complex, which includes photoreceptive cells controlling circadian rhythm, is, for instance, confined to the left brain side in zebra fishes. Left- and right-hemispheric Hb on the other hand display prominent differences in size, connectivity pattern, and subcellular organization. Only the left Hb receives input from the pineal complex, while the right one receives input from specific olfactory bulb fibers (Concha et al. 2012). Accordingly, most neurons that respond to odors are located on the right Hb, while left Hb neurons preferentially respond to light stimuli. Loss of typical brain lateralization leads to impaired sensory processing (Dreosti et al. 2014) and results in enhanced fear behavior (Facchin et al. 2015).

The functional impact of projection asymmetries is exemplified in the lateralized visual system of birds like chicks and pigeons. In both species, a neuroanatomical element of lateralized visual processing is represented by a difference in projection strength between the two hemispheres. In pigeons, higher bilateral input to the left brain side is related to a more complete representation of information from both visual hemifields (Güntürkün and Ocklenburg 2017; Manns and Ströckens 2014).

Synaptic asymmetries are reported for the mouse hippocampus. Synapses between CA3 and CA1 neurons display left-right differences in spine morphology, NMDA receptor density, and synaptic plasticity depending on whether afferents originate in the left or right CA3. Disruption of these structural differences is correlated with impaired spatial learning and working memory (Shipton et al. 2014).

## Ontogeny of Hemispheric Specialization

Structural and functional neuronal asymmetries emerge by complex gene-environmental interaction during ontogeny. Genetic factors provide signals, which establish a basic framework for asymmetrical processing. Environmental cues modulate the inherent pattern by influencing final differentiation of neuronal networks. Thereby activity-dependent processes modify the number and structure of synapses or change local and long-range connectivity pattern. Long-lasting effects might be mediated by epigenetic mechanisms, which constantly modify gene expression pattern (Güntürkün and Ocklenburg 2017).

Neuronal asymmetry formation starts very early during development when body axes of the embryo are determined under the control of complex gene signalling cascades, which are highly conserved in bilateral animals. Already during this phase, the described asymmetries of *C. elegans* neurons are determined. In vertebrates, these genes determine asymmetry of inner organs with the heart on the left or the gallbladder on the right side but also induce asymmetrical bending of the spine resulting in an asymmetrical

body position of the embryo. A central component is the nodal signalling pathways, which plays a second critical role in inducing neuronal left-right differences in the brain by determining, for instance, epithalamic asymmetries (Concha et al. 2012; Signore et al. 2016). These left-right differences can be, however, modified by visual stimulation (Andrew et al. 2009).

The critical impact of sensory experience is exemplified in the visual system of chicks and pigeons, which develops anatomical as well as functional asymmetries in response to asymmetric light stimulation (Güntürkün and Ocklenburg 2017; Manns and Ströckens 2014). Due to the genetically controlled bending of the spine, embryos turn their head so that the right eye is close to the light-translucent eggshell, while the left eye is covered by the body. As a consequence, the right eye and, hence, the left hemisphere are more strongly activated and induce the development of anatomical left-right differences, which are related to the functional dominance of the left hemisphere for visuomotor control and which enable efficient interhemispheric cooperation (Manns and Römling 2012).

Apart from sensory stimulation, hormones (like corticosteroids and sex hormones), social experiences, cultural influences, or stress level can affect asymmetry formation and, hence, functional lateralization pattern. Sex hormones impact the organization of lateralized brain structures and modulate hemispheric-specific processing mode as well as degree of interhemispheric communication. Consequently, males and females often display differential functional lateralization pattern (Ocklenburg and Güntürkün 2017).

## Testing Hemispheric Specializations in the Lab

There are many ways to investigate hemispheric specialization pattern in different species (for a detailed overview, see Rogers and Vallortigara 2017):

### 1. Behavioral Observation

The easiest way to detect hemispheric specialization is behavioral observation since

asymmetrical behavior indicates a lateralized motor strategy, which is controlled by the dominant brain hemisphere. Preferential limb use, turning of the head or tail, or complete body or asymmetrical interactions with objects or conspecifics can be easily recorded and quantified. True dominance for motor control, however, is only proved when a preference is constant across time and consistent between different tasks.

One may analyze lateralized behavior of individuals while conducting a specific task under controlled conditions in the lab. These are, however, eventually artificial situations, which may not occur within the natural environment of a species. Accordingly, more and more studies report asymmetrical behavior obtained from observations in the wild or zoo.

### 2. Sensory Input Restriction

For a deeper understanding how behavioral asymmetries are related to hemispheric specialization, it is often helpful to direct sensory input to one hemisphere. When paired sense organs project to only one brain side (fibers of retinal ganglion cells, for instance, cross completely in many vertebrate species; while in bees, input from one antenna projects to ipsilateral antennal lobe), separate testing of the hemispheres can be easily conducted by temporarily occluding one eye, ear, nostril, or antenna. Honey bees, for instance, display better olfactory conditioning when trained with the right antenna (Frasnelli 2013). It is also possible to investigate if an individual displays performance differences depending on the brain side in use (Fig. 4). The better hemisphere is then the dominant, specialized one, which may also dominate under bihemispheric test conditions (Fig. 3).

### 3. Unihemispheric Lesions

Comparing left- and right-sided performances indicates hemispheric specializations but does not unravel the underlying structural organization. Lesion studies are suitable tools to unravel asymmetrical participation of specific brain areas. When an individual does not show a behavior anymore after damage of a particular neuronal structure, then this target area must be critically involved in the

**Hemispheric Specialization, Fig. 4** Differential types of lateralization pattern (orange circles indicate left-hemispheric dominance; green circles right-hemispheric dominance): (a) when individuals of a population do not possess a preferential hemisphere controlling a task, no asymmetry is present; (b) individual-level asymmetry

means that the left hemisphere is consistently dominant for one half of the population and the right one for the other half; (c) population-level asymmetry means that a majority of animals display consistent dominance of one hemisphere for a specific task (e.g., the left one) (based on Ocklenburg and Güntürkün 2017)

H

generation of this behavior. Permanent lesions or transient silencing of left- and right-sided structures shed therefore light on left- and right-hemispheric contributions on cognitive task performances. Hemispheric-specific deficits point to the functional dominance of the lesioned brain side. The pioneering work of Fernando Nottebohm (1971), for instance, demonstrated a left bias for song production in chaffinches (*Fringilla coelebs*) by cutting the left or right tracheosyringalis nerves, which innervate the syrinx as the vocal organ in songbirds. Only cutting the left nerve led to impairment of song production.

#### 4. Neurophysiological Measures

Knowledge about the participating brain regions does not explain the neuronal mechanisms underlying hemispheric specialization. Electrophysiological recordings allow investigating differential computation modes of left- and right-hemispheric circuits. Comparing the response pattern of visual neurons of pigeons, for instance, indicates a more elaborated processing of visual information within the left visual forebrain, which is related to the functional dominance of the left hemisphere for visuomotor control (Freund et al. 2016).

Additionally, brain imaging techniques provide noninvasive methods to investigate processing differences of left- and right-

hemispheric areas. This method is the major technique in human asymmetry research, but first studies used these techniques to investigate hemispheric differences in animal species, too (e.g., Jonckers et al. 2015).

## Herbert Spencer

Vincent Barnett

Independent Scholar, London, UK

### Definition

Herbert Spencer (1820–1903) was a Victorian natural and social scientist polymath whose most notable contributions were as a theorist of biology and psychology, although he wrote many other works in various disparate fields. He published articles on the theory of evolution as a general process before

Darwin's *On the Origin of Species*, but he did not specify any concrete or verifiable mechanisms by which it took place, instead being content to define evolution simply in terms of an ongoing differential complexity in biological forms, homogeneity being transformed into heterogeneity (Spencer 1852a, 1857; Hull 2002, E-12).

### Introduction

Spencer's two most representative works *The Principles of Biology* (1864) and *The Principles of Psychology* (1855) went through numerous revised editions across the second half of the nineteenth century, including some large-scale expansions from single to multiple volumes, and if book sales are an important measure of scientific achievement then Spencer was a first-year success. His first book was entitled *Social Statics* (1851) and a year later he published an account of population and animal fertility (Spencer 1852b), indicating an early interest in the natural world. Other significant works by Spencer included book-length accounts of sociology, ethics, and the state, in which he promoted a liberal conception of freedom defined by him through a law of equal freedom allocated to each individual person in a given society.

However, as there are numerous general accounts of Spencer's work taken as a whole for readers to consult (for example, see Francis 2007), this relatively short entry on Spencer will concentrate mainly on those aspects of his work that are relevant to evolutionary psychology and to an understanding of animal cognition, as these are the focus of this particular encyclopedia, but before this, his wider scientific importance requires brief consideration.

### Spencer's Scientific Importance

By far Spencer's single greatest and most enduring claim to intellectual fame is that he coined the term "survival of the fittest" in 1864, which was then keenly adopted by Charles Darwin, firstly in his book *The Variation of Animals and Plants*

under *Domestication* in 1868 and then in the fifth edition of *On the Origin of Species* published in 1869 (Bowler 2008, p. 115, 120). This phrase has been criticized by some as the most famous tautology in the scientific world, as (by definition) those that survive are seen also as the very fittest.

However, although Spencer was almost as well-known as a biological theorist as Darwin was in his own time, Spencer's current reputation has been entirely eclipsed by that of Darwin, to the point that the phrase "who now reads Spencer" is currently as ubiquitous as his term "survival of the fittest." Spencer is also often blamed for the distortion of the Darwinian approach that was promoted as Social Darwinism, and which crassly and erroneously aimed to apply the "survival of the fittest" idea as a form of social policy within contemporary human societies.

Darwin judged that Spencer's theoretical works were usually too abstract to be of any use to him in his own work on understanding evolution, dismissing one of Spencer hypothesized general laws with the rather unflatteringly evaluation: "speculation on the subject is almost useless" (Darwin 1872 [1859], p. 100), and the scientific status of Spencer's law-like speculations were questioned even in his own time (Hull 2008, p. 19). Spencer's works were nevertheless of some importance in promoting the idea to the wider public that the natural world had undergone a process of continuous evolution over a geological timescale.

For example, it is evident from his writings that – for Spencer – evolution was the central originating process across the whole natural world, declaring that: "Life under all its forms has arisen by a progressive, unbroken evolution" (Spencer 1855, p. 578). He explained: "For myself, finding that there is *some* positive evidence of evolution in the modifications undergone by all organisms under changed conditions, in the development of every living creature – I adopt the hypothesis until better instructed" (Spencer 1855, p. 578). Elsewhere, Spencer defined life as the "continuous adjustment of internal relations to external relations," his formulation of the process of organisms adapting to their environments (Spencer 1855, p. 374).

## Spencer on Cognition

In addition to promoting the general concept of evolution, Spencer was a nineteenth-century advocate of cognitive science. He defined cognition as a "group of inner relations" that corresponded to external or outer relations, with a false cognition occurring when the internal relations do not match the external relations accurately (Spencer 1855, p. 471, 470). He explained further on cognitive processes that:

The cognitions of exact science are distinguished from interior cognitions in this; that the mental process involves a symbol answering to every constituent of the phenomenon. For this infallible guidance to be had, however, requires that *all* the elements of the relation be cognized. Whenever a group of inner relations, a cognition, is completely conformed to a group of outer relations, a phenomenon, by a rational process – whenever there is what we call an understanding of the phenomenon; it is that the genesis of the phenomenon is, in a sense, paralleled by the genesis of the cognition. (Spencer 1855, p. 471: italics in the original)

Spencer clearly distinguished between the cognitive and the emotive faculties of perception as a strongly marked contrast, but he then confirmed that all mental phenomena (both reason and emotion) were the evolutionary result of "correspondence between the organism and its environment" (Spencer 1855, p. 584).

In addition to focusing attention on cognitive function, Spencer recognized in outline the "localization of function in the cerebrum" and other parts of the brain, declaring that different parts of the cerebrum served different kinds of specialized mental process: "every bundle of nerve-fibres and every ganglion, has a special duty" (Spencer 1855, pp. 607–608). He even anticipated (in vague terms) the idea of a psychological mechanism, defining a mental faculty as an "internal plexus of nervous relations" with a specific focus (Spencer 1855, p. 609; Fodor 1983, p. 1983). Spencer also wrote explicitly on "Mental Evolution in Animals" (Spencer 1884), reviewing George Romanes's book on the subject (Romanes 1883), and it has been suggested that Romanes's discussion of mental activity in this book "depended largely on Spencer's

psycho-evolutionary theory” (Richards 1987, p. 348), to which attention is now turned.

## Spencer as the First Evolutionary Psychologist

It is customary for some scholars to declare that Darwin is the true originator of the evolutionary approach to understanding psychology. However, Darwin himself said something quite different on the topic, declaring in the sixth edition of *The Origin of Species* as follows: “In the future I see open fields for far more important researches. Psychology will be securely based on the foundation already well laid by Mr. Herbert Spencer, that of the necessary acquirement of each mental power and capacity by gradation” (Darwin 1872 [1859], p. 428). Thus, according to Darwin in 1872, it was Spencer who was the true originator of the then futuristic subject of evolutionary psychology.

It could be argued that Darwin was just playing lip service to a possible Spencer claim for priority, either out of politeness or to avoid any potential conflict, but the subject certainly merits further investigation. Darwin specified directly which Spencer book he had in mind in his “Historical Sketch” from the *Origin*: “The author (1855) has also treated Psychology on the principle of the necessary acquirement of each mental power and capacity by gradation” (Darwin 1872 [1859], p. xix), this being a clear reference to the first edition of *The Principles of Psychology* (Spencer 1855). This book contained a substantial chapter on “Instinct” and was published sometime before the first edition of Darwin’s *Origin*. Does this work, as Darwin suggested, in fact provide the first foundations of the subject of evolutionary psychology? The next section will attempt to answer this question directly.

## Spencer on Instinct

In the preface to *The Principles of Psychology*, Spencer explained that his aim in the book was to describe both “the evolution of Life in general”

and “the nature and genesis of the different modes of Intelligence, in terms of the relation which obtains between inner and outer phenomenon” (Spencer 1855, p. iv), this later aim involving the comprehension of the evolution of mind and of the instincts contained within it.

Spencer defined instinct – or what he called the mentally generated actions of the nervomuscular apparatus – as a compound reflex action that, in its initiation, combined a number of separate stimuli in a complex sequence, which was then realized through the functioning of automatic connections of nervous actions. The higher the instinct in operation, the more complex were both the directive and executive coordinations involved in its execution (Spencer 1855, pp. 539–540, 542, 548). He then explained that, by the evolution of accumulated experiences, these compound reflex actions developed out of the simple reflex ones, this particular evolution being what Spencer called the experience hypothesis.

One key passage from *The Principles of Psychology* on the experience hypothesis linked the evolution of intelligence by the multiplication of experiences, to inner relations corresponding with outer relations resulting from a continued registration of these experiences (Spencer 1855, p. 551). The passage was as follows:

we see that the conclusions deducible from the experience-hypothesis, are in harmony with such facts as we possess. We see that the evolution of instincts, as resulting from experience, is quite comprehensible. We see that, if produced by experience, this evolution must proceed from the simple to the complex; which is the indication of positive evidence so far as it is attainable. And we see that by a progression thus wrought out, instinct must in the end insensibly pass into a higher order of psychical action; which is just what we find it to do in the higher animals. (Spencer 1855, p. 553)

This passage fairly obviously contains the germ of the idea that instincts originate by evolutionary processes, although the Darwinian concept of evolution by natural selection had (in 1855) yet to be publicly outlined.

The following key passage from Spencer’s *The Principles of Psychology* contains an even clearer formulation of the idea of the natural evolution of instincts as psychological phenomena. He

declared that he formulated “the law that habitual psychical successions entail some hereditary tendency to such successions, which, under persistent conditions, will become cumulative in generation after generation, to supply an explanation of all psychological phenomena” (Spencer 1855, pp. 578–579). Although it is certainly true that Darwin was pursuing an evolutionary approach to understanding instincts well before 1855, as his notebooks clearly illustrate – “new instincts can originate” (Darwin 1974 [1838], p. 284) – Spencer was first to actually publish a book on this topic, 4 years before the publication of the first edition of *On the Origin of Species* in 1859 (Spencer 1855). Darwin’s modification of the passage in the *Origin* on “the necessary acquirement of each mental power and capacity by gradation” to include Spencer’s claim to priority thus makes sense in historical terms.

In addition, in *The Principles of Psychology*, Spencer began to attempt to plot the relation between instinct and other mental processes such as reason. He stated on this relationship that:

How then can any particular phase of complexity or infrequency be fixed upon as that at which Instinct ends and Reason begins? Will any one be so absurd as to say, that so long as the external phenomenon responded to does not involve more than twenty elements, the response is instinctive; but that if it involves twenty-one the response is rational? (Spencer 1855, p. 565)

Spencer suggested that what he called the progressive complication of instincts involved a diminution of their automatic character and a greater involvement of reason and memory, although this complication process was asserted by him on purely speculative grounds. Overall, Spencer’s attempt to ground an understanding of mental processes and the subject of psychology in purely natural science terms was innovative in its day.

## Conclusion

As has already been previously outlined and as has been further argued in this entry, Spencer was the first published author to attempt to provide

(in outline at least) an evolutionary account of the origin of mind, mental processes, and instincts that is consistent with the precepts of contemporary evolutionary psychology (Carneiro 2012, p. 518; Rylance 2000). Of course Spencer’s account was very basic and general in nature, and Darwin soon provided a much more sophisticated account of instincts and mental evolution in the *Origin* (and also in *The Decent of Man*), but the fact that Spencer’s work reinforced Darwin’s naturalistic approach to understanding cognition rather than countered it was of some significance in historical terms at least in the mid-1850s. Arguably, apart from his invention of the phrase “survival of the fittest,” Spencer’s pioneering work on the evolutionary understanding of mental processes was his most enduring scientific achievement.

## Herbert Terrace

Greg Jensen  
Columbia University, New York, NY, USA

**Herbert S. Terrace** is a professor of psychology at Columbia University. He is best known for his experimental work in comparative and animal cognition, particularly on the topics of errorless learning, serial learning, and metacognition, as well as for attempting to train a chimpanzee to use sign language, and for his analysis of the evolution of language.

## Early Life and Education

Terrace was born November 29, 1936. He received an undergraduate degree in psychology from Cornell University in 1957 and a PhD from Harvard University in 1961, advised by B. F. Skinner. Among his early influences, Terrace credits Skinner's approach to operant conditioning as influencing him substantially. However, two other figures (S. S. Stevens and

H. M. Jenkins) also shaped his early views (Terrace 2010b), motivating his initial research interest in dissecting the role of psychophysical discriminations in operant behaviors. Work in this domain gradually revealed the limitations of a purely behavioral approach and demonstrated the effectiveness of combining cognitive theories with rigorous experimental design.

## Stimulus Discrimination in Operant Research

Terrace's first major interest was the role of errors (formally, responses to S-) in discrimination learning. Contrary to the principles of operant learning (as well as current assumptions of prediction-error-driven learning), Terrace's early work showed that subjects (mainly pigeons) could learn relatively difficult stimulus discriminations between two similar wavelengths of light while making almost no errors during training (Terrace 1964). Errorless learning was accomplished by initially presenting highly discriminable stimuli, such that learning could occur within a trial or two, and then gradually reducing the difference between S+ and S-.

Systematic study of discrimination learning (reviewed in Terrace 1972) helped to resolve a crucial question of the time: Under what circumstances is S- aversive? In classic Skinnerian procedures, pigeons presented with S- routinely produced behaviors collectively described as "frustration," such as general agitation and, occasionally, aggression toward the stimulus, suggesting that S- was intrinsically aversive. However, frustration was not observed during errorless learning. Through a series of careful experiments, Terrace showed that the aversiveness of S- was contingent on a history of unrewarded responses to S-. It was not aversive if subjects learned to discriminate without errors.

Using a similar gradual training approach, Terrace showed that other aspects of discrimination learning were also contingent on a subject's learning history. For example, it was well established that if an animal was trained to respond to a specific wavelength of light (S+), there was less

responding to wavelengths greater than or less than S+. Following discrimination learning with errors, the peak shifted to an untrained wavelength, away from S-. However, peak-shifts did not occur following discrimination learning without errors.

Terrace also collaborated on several projects to investigate the phenomenon of autoshaping, whereby the presentation of S+, followed by non-contingent reward, caused subjects to respond to it, a circumstance in which the subject shaped its own behavior. These efforts yielded two important conclusions. One was that the logarithm of trials to acquisition was a linear function of the log duration of the intertrial interval. This meant that the ratio between stimulus duration and the intertrial interval was constant (Gibbon et al. 1977). A more unsettling conclusion was that the basic stimulus-response relation at the heart of Skinner's operant conditioning paradigm was incomplete because it failed to take biological constraints into account.

## Project Nim

In December 1973, Terrace acquired an infant chimpanzee named Nim Chimpsky and started "Project Nim," an intensive effort to teach sign language to a nonhuman animal (Terrace 1979). Project Nim asked if a chimpanzee who was immersed in an environment that used American sign language (ASL) could not only learn individual words, but also learn to construct grammatical sentences. Although several primate language studies had been underway since the late 1960s, most had an informal structure and no consistent framework for data acquisition (Terrace and Bever 1976). Project Nim was different. In addition to continuous social interaction with a large team of volunteers, Nim also received extensive training in a controlled classroom setting, during which he was videotaped. This provided Terrace and colleagues with a representative corpus of the signs Nim and his teachers exchanged.

This video archive was essential to understanding the nature of Nim's utterances. At the project's conclusion in 1977, Terrace and colleagues set

about analyzing the data, and seemed to have enough evidence to argue that Nim had a rudimentary grammar. However, during subsequent slow motion analyses of the same videotapes, it became clear that Nim's multisign utterances were prompted by his teachers. In virtually every instance, the videotapes showed that Nim's teachers unwittingly produced the relevant signs a fraction of a second before Nim did. Furthermore, all of the thousands of utterances they recorded were imperative. None were declarative. Thus, to the question, "Can an ape create a sentence?" Terrace and colleagues concluded that the answer was "No" (Terrace et al. 1979).

## Animal Cognition and Serial Learning

In the wake of Nim's failure to acquire grammar, it was nevertheless clear that nonhuman animals were able to solve sophisticated discrimination problems in ways that could not be satisfactorily explained by operant or Pavlovian means. Consequently, Terrace subsequently asked, what can an animal learn *without* linguistic competence?

Terrace's extensive study of the nuts and bolts of operant conditioning revealed that many features of learning, which were taken to be intrinsic by behaviorists, were contingent on a subject's learning history (Terrace 1984a). It also became increasingly difficult to account for much learned behavior without reference to the then-emerging cognitive terminology of memory, attention, and representation. During the early 1980s, Terrace played an instrumental role in creating the subfield of animal cognition, a new area of comparative psychology (Roitblat et al. 1984).

Of particular interest was the topic of sequence learning. Terrace showed that Skinner's attempts to account for human language acquisition in terms of operant chains failed because a stimulus-driven account could not explain how humans and other animals processed simultaneously presented stimuli. That insight inspired the development of the simultaneous chaining procedure (SCP), an experimental paradigm in which subjects learned to respond, in a particular order, to arrays of simultaneously visible stimuli

(Terrace 1984b). In contrast to Skinner's successive chaining paradigm, in which performance could be explained by reference to external stimuli, the execution of a simultaneous chain required subjects to represent the ordering of the stimuli during the execution of a sequence. In that sense, an animal's execution of a simultaneous chain provided an intermediate step between association and linguistic models of behavior (Terrace 1987).

The study of serial learning in nonhuman animals presented a major opportunity for comparative psychology. Although it isn't possible to study the evolution of human language directly, because of a lack of natural counterexamples, serial learning in nonhuman primates might provide insight into evolutionary precursors (reviewed in Terrace 2010a). With that goal in mind, Terrace's early SCP work transitioned from pigeons to rhesus macaques in the early 1990s. With a series of collaborators, Terrace investigated the flexibility of serial representations (Chen et al. 1997), evolutionary precursors to numerical reasoning (Brannon and Terrace 1998), the emergence of serial expertise (Terrace et al. 2003), imitation of sequences (Subiaul et al. 2007), and task switching (Avdagic et al. 2014).

More recently, Terrace sought to systematically relate SCP to the transitive inference (TI) paradigms. TI is another paradigm for studying serial order, in which subjects are presented with only two stimuli at a time and must choose which one comes earlier in an implied list (Merritt and Terrace 2011). Unlike the SCP, in which the full list is visible on each trial, and in which subjects must explicitly respond to all of the items in the correct order, TI requires that subjects learn lists implicitly. Terrace and colleagues demonstrated that despite such different task demands, knowledge of a list's serial order is transferred both ways between SCP and a TI task (Jensen et al. 2013), such that each task can be used to train a list order that can then be exploited within the other paradigm. Terrace's current work on serial order uses the SCP and TI paradigms to probe their common underlying cognitive mechanisms with tools of computational and experimental neuroscience (Jensen et al. 2015; Tanner et al. 2017).

## Metacognition

In the early 2000s, Terrace began to study comparative metacognition (Terrace and Metcalfe 2005; Metcalfe and Terrace 2013). As with his earlier work on primate language, Terrace was concerned that many published studies that made dramatic claims about nonhuman abilities lacked enough experimental rigor to rule out simpler explanations (Terrace and Son 2009). For example, in order to distinguish metacognition from unrelated skills, Terrace and colleagues demonstrated that nonhuman subjects could readily transfer a hint-seeking ability on which they were trained to novel tasks (Kornell et al. 2007).

Of particular importance was the introduction of new paradigms in which nonhuman subjects could be trained to strategically express confidence about risky behavior. There were two variations. An animal could make use of metacognitive information prospectively (prior to making a choice) or retrospectively (after making a choice, but before receiving feedback). Terrace and colleagues investigated both possibilities in a delayed match-to-sample task using a token economy (Morgan et al. 2014). Tokens were visible on a touch screen throughout the task. When a sufficient number of tokens had been obtained, they automatically produced a food pellet. Subjects were differentially rewarded for high- and low-risk confidence judgments following correct or incorrect responses on a discrimination problem. On each trial, they could make a high-stakes bet (+3 tokens if correct, -3 tokens if incorrect) or a low-stakes bet (+1/-1 tokens). In the retrospective condition, subjects were first shown a target. Following a short delay, they had to choose that target from a set of distractors. They were then required to place a bet and were immediately given the appropriate reward or punishment. Consistent with the metacognitive hypothesis, monkeys preferred low-stakes bets on trials on which they were less likely to be accurate. In the prospective condition, subjects were shown the target, then made their wager after a brief delay, and finally ended the trial with the memory test. In both the prospective and the retrospective conditions, subjects placed their bets strategically.

## The Evolution of Language

The negative results of Project Nim prompted Terrace to ask two related questions (Terrace 1985). First, why couldn't chimpanzees learn to make declarative statements? Second, how did words evolve? His recent analyses of hominid ancestry and of the development of linguistic skills of human infants led him to conclude that chimpanzees weren't able to learn to name objects because they lacked the ability to engage in two foundational precursors: intersubjectivity and joint attention (Terrace 2011). Further, language requires the capacity of an individual to have a theory of mind that recognizes the capacity of another individual to understand verbal utterances (Studdert-Kennedy and Terrace 2017; Terrace forthcoming).

## Introduction

The sun is the ultimate source of energy, and plants are capable to trap the visible spectrum of sun's radiation. Therefore, plants are known as photosynthesizers, which have the ability to

synthesize food in the presence of sunlight. The entire living world relies directly or indirectly on this photosynthetic produce and gets energy for their various life processes; therefore the plants are considered as producers or photoautotrophs (Raven 2019). The energy obtained by the plants gets transferred to a heterotrophic organism that eats plants, subsequently to another organism relying only on animals for their feed. Thus, the animals are heterotrophic and known as consumers (Raven 2019). Therefore, there is a successive relationship among the organisms where one organism relies on other for its food (Fig. 1). Each living organism is connected with each other in a straight chain for food and occupies its specific position, known as trophic level in this linear series (Fig. 1). This succession of living organisms, known as food chain, is connected as producers–primary consumers–secondary consumers–tertiary consumers at first trophic level, second trophic level, and third trophic level or even higher (Figs. 1 and 2). Subsequently, this establishes a natural consumption link, the food webs via interconnected food chains in an ecosystem (Raven 2019).

## Herbivores and Herbivory

An herbivore is simply an exclusive plant eater. A heterotrophic animal that feeds only on different types of plants (i.e., algae, bryophytes, herbs, shrubs, and trees) or plant parts such as leaf, stem, root, fruits, seeds, etc., is known as herbivore, and the feeding strategy of herbivores is known as herbivory. Herbivores are integral key elements of food chains/webs that transfer photosynthetic produce, being a link between the primary producers and secondary consumers (Pape and Löffler 2012; Figs. 1 and 2). Herbivores, therefore, play a pivotal role in maintaining equilibrium in an ecosystem by being the first one to eat photoautotrophs and transfer the energy ahead in the living world (Figs. 1 and 2).

## Diversity of Herbivores

There is a great diversity of plant species in the living world, which is largely responsible for the

**Herbivore, Fig. 1** Flow of energy and food in an ecosystem: a food chain

**Herbivore, Fig. 2** Feeding strategies of the organisms in an ecosystem

diversity of the herbivores, i.e., animals that feed on them. Subsequently, there is a great diversity of herbivores that include insects, mollusks, and mammals and may range from small aphids (an insect) to snails and large elephants, rhinoceros, gorillas, and also the endangered red panda (Fig. 3).

Among all, insect herbivores are the most common. It has been expected that around half of the insects are herbivores that includes millipedes, mites, worms, and some other species of insects. Several large insect groups are totally plant feeders that include butterflies, gall wasps, leaf beetles, leaf-mining flies, moths, plant bugs,

weevils (e.g., a common cotton boll weevil), etc., and exert a great threat to agricultural crop.

Among mollusks, most of the Chitons, calcareous marine animals and some gastropods are grazing herbivores, e.g., snails, etc. Besides, crabs, ducks, krill, sea slugs, sea snails, sea urchins, parrot fish, surgeonfish, etc., are some other aquatic herbivores.

Mammals include small- and large-size organisms that may be further categorized as rodents, ruminants, and non-ruminant animals (Fig. 3). Rodents are mammals of the order Rodentia, which are characterized by a single pair of continually growing incisors in both of the upper and lower jaws (Single et al. 2001). Rodents include mice, rats, prairie dogs, squirrels, chipmunks, chinchillas, guinea pigs, porcupines, gerbils, beavers, hamsters, capybaras, hares, rabbits, and pikas. Most rodents are herbivorous which feed exclusively on plant materials such as seeds, leaves, stems, flowers, and roots.

Plants have many complex structures such as leaves, stems, rhizomes, tubers, roots, flower parts, fruits, seeds, etc., that animals have to overcome in order to use plants as a source of food. Besides, the plant cells are encased by a tough cell wall, made of complex polysaccharides such as cellulose, lignin, pectin, etc., that makes a plant tough to digest. Among all ruminant and non-ruminant mammalian herbivores, cellulose, a complex polysaccharide molecule of linear chain of thousands of glucose molecules, is the major source of food component, and mammals do not have enzymes to digest this complex molecule.

**Herbivore, Fig. 3** A generalized cataloging of terrestrial herbivores

H

Ruminating mammals having specialized multi-chambered stomach include antelopes, buffaloes, cows, deer, gazelles, giraffes, goats, sheep, etc. (Fowler 2010). They rely on certain symbiotic microorganisms for breakdown of the complex molecule, cellulose, into simple monosaccharide molecules, glucose, to obtain energy by fermenting principally through microbial actions. Ruminant mammals have this cellulose digesting microorganism living in symbiotic relationship in one of the chamber, probably the largest one, rumen. The largest chamber, rumen, also allows rumination in such mammals where the partially digested food to regurgitate back in the large cheek pouches to rechew the cud. The food is further digested in other chambers of their huge multi-chambered stomach.

Non-ruminant mammals having single chambered and relatively small stomach including donkey, elephants, hares, horse, kangaroos, mules, rabbits, zebras, etc., also depend on plants exclusively for their feed. These mammals and even rodents also have some different way of digesting this complex molecule, cellulose. The cellulose-

digesting microorganisms live in a large pouch known as cecum that lies at the posterior side of the small intestine in such non-ruminant mammals. Such organisms do not regurgitate the food back to cheek pouches. However, some of the non-ruminating mammals, like hares and rabbits, show coprophagy, a habit of eating their feces back thereby allowing them another way to digest cellulose. Such animals are known as coecophagus.

Besides, various complex plant structures may vary from species to species and thus provide wide range of feeding opportunities to herbivores, eventually reflecting the wide diversity of herbivores and plants too (Fig. 4). Therefore, herbivores can also be categorized as:

- **Algivores:** Algivores herbivore gets food from Algae. Algivores include Crab, Sea urchin, Krill, Sea snail, flamingo, Parrotfish and Surgeonfish
- **Nacterivores:** They feed on Nectar, ex. Honey possum
- **Mucivores:** They feed on plant fluids, i.e. Sap. It includes Aphids

**Herbivore, Fig. 4** A specialized cataloging of herbivores based on feeding habit

- **Palynivores:** Their food materials are pollen grains, ex. Bees
- **Folivores:** They feed on leaves of plants it include Koalas
- **Frugivores:** It includes those herbivores which gets food from fruits, ex. Ruffed Lemurs
- **Granivores:** Their food materials are seeds, ex. Hawaiian Honey creepers
- **Xylovores:** They feed on woods, eg. Termites

### Herbivory: Relationship Between Plants and Herbivores

The “battle” between plants and herbivores is likened to an arms race and has led to strong relationships between many herbivores and plants. Such relationship ranges from animals feeding only on particular plant groups or species; this kind of specialization where an animal relies on a certain plant or plant group to grow is referred to as “plant-host specificity.” Herbivores are often smaller than the plants on which they rely for their food; thus, they may damage a single plant or crop over days or weeks however without killing it but causing serious economic losses. Besides, an elimination of a particular plant species or group may result in the loss of several animals from an ecosystem. To understand the relationship between plants and animals is really important for the survival of an ecosystem in a better way.

### Herbivory: Adaptations and Modifications Among Herbivores

The herbivorous animals have developed specialized physical features and feeding strategies to utilize fibrous plants as a source of food. Many

special features and adaptations are exhibited by the herbivores that allow them to access the complex structures among autotrophs such as:

- Grazing and browsing herbivores have a heterodont pattern; they have evolved grinding teeth to break up tough plant tissues and use their six lower incisors to crop off grass and leaves and make use of the flat and wider pre-molars and molars for stripping leaves and grasses and as grinding surfaces to break up the cellulose of the vegetation they eat.
- Cheek pouches to store the engulfed food material (e.g., mammals).
- Specialized digestive system with multi-chambered stomach where microorganisms are accommodated to help to digest the food through fermentation. Ruminants (sheep, goats, deer, giraffes, camels, and cattles such as cow, buffalos, etc.) can regurgitate its partially digested food, known as cud, and chew it again.
- They have long small intestine generally that is specialized for absorbing proteins, which are in short supply in their diet.
- The trunk, a flexible, gripping nose of the elephant.
- Long tongue and long neck to get to leaves on long trees (e.g., giraffe).
- Continuously growing upper and lower incisors in cecotrophs. They can ingest their partially digested feces back to digest it again and get nutrients (e.g., hare and rabbit).
- Modified legs for digging and to access rhizomes, tubers and roots, etc.
- Modified mouthparts and legs especially among insects, cutting and chewing mouthparts (e.g., beetles) or piercing mouthparts (e.g., wasp ovipositor), sawlike mouthparts

- (e.g., sawfly ovipositor), and several other appendages like claws, spines, or suckers that allow some herbivores to cling the surface and giving them to access to internal structures that allow them to feed on plants.
- Wings that help them to reach at the top of the highest plant (e.g., insects).

## Herbivory: Defense Systems Among Plants and Herbivores

Plants have evolved several morphological and phytochemical defense systems to deter the herbivores. Plants have different developmental stages of growth such as new leaves are growing and roots are extending, while elsewhere on the same plant, leaves are aging and roots are decaying. Thus, during growth and development, plants change their morphology and phytochemical structures. Therefore herbivores and plants develop some resistance against each other by developing:

### Defense Systems Among Plants

#### Morphological Defense Systems in Plants

- Development of trichomes – Numerous hair-like appendages, i.e., trichomes, develop on the surface of stems, leaves, and roots that repel some of the small-sized herbivores, chiefly the insects. Interestingly, some are glandular trichomes which secrete certain chemicals that are lethal to small-sized herbivores.
- Plants also use thorns, spines, prickles, and sticky plant parts that play an important role to deter some of the herbivores.
- Even in some plants, after grazing leaf meristems may grow out and replace the lost part.

#### Deposition of Complex Chemical Structures in Plant Cell Walls

- To maintain their physical structure and support, plants use complex compounds such as cellulose, pectin, and lignin. These compounds are tough, water insoluble, and also difficult to digest.

- Some plants deposit silica, sticky resins, and other compounds in leaves and stems that make their surface abrasive to avoid themselves eaten by the herbivores.

### Phytochemical Defense System in Plants

Plants produce many active compounds or chemicals for defense against herbivores that may deter herbivores from feeding or kill them (Fraenkel 1959). These phytochemicals, commonly known as secondary metabolites (alkaloids, essential oils, terpenes, phenolics, tannins, etc.), are differentially synthesized in small or large quantities in different plants or plant parts in response to initial plant damage by the herbivores and thus herbivores avoid eating such plants or plant parts further (Bennett and Wallsgrove 1994; Maffei et al. 2012).

Plants produce ethylene, jasmonates, and salicylates on grazing or eating that act as phytohormones and signaling agents to induce several other defense mechanisms in plants (Maffei et al. 2012).

Even in some plants, the nectar and other secretory glands secrete sweet nectar, oils, waxes, latex, essential oils, some scented and aromatic substances, etc. to lure and repel the bees, flies, moths, and some other insects, birds, and some animals too, thus maintaining the prey–predator ratio, keeping themselves protected and away from some herbivores (Bennett and Wallsgrove 1994; Maffei et al. 2012).

### Defense Systems Among Herbivores

Herbivores too have a number of feeding strategies to overcome these complex plant tissues and chemical structures such as:

- Eating tough or complex plant tissue by using chewing mouthparts.
- Avoiding complex plant tissue by eating soft internal tissues.
- Eating complex plant tissue by forming alliances with other organisms.
- Avoiding complex plant tissue by eating plant fluids.

- Some herbivores either evolve resistance against some secondary metabolites of the plant or get shift to some other resource to avoid inter- or intraspecific competition.

## Significance of Herbivory

- Herbivory plays foremost and an important role in maintaining food chain of an ecosystem.
- Herbivores are important ecosystem engineers having ability to make changes in grazing plant communities, modifying habitat structures, and altering nutrient flows (Asner et al. 2009; Olf and Ritchie 1998; McNaughton et al. 1997; Jones et al. 1994).
- Herbivory can have significant impacts on the composition, structure, and diversity of plant communities on earth, their habitat, and health.
- It avoids the overcrowding of the plants with each other and influences plant communities in terms of individual plant's growth and development.
- It may increase the chances of successful seedling growth.
- It improves conditions for plant growth by pruning plants and allow light to reach the surrounding area.
- It increases and maintains soil fertility contributing to the plant litter and the nutrient pool in soil by nutrient recycling from plants.
- Increases in nutrient uptake and productivity of plants.
- Plant can be detoxified by herbivores (Dearing et al. 2000).
- It also improves plant defense mechanism after initial plant damage from herbivory.
- Herbivores also have cultural, social, and economic importance for the people (Zachrisson 2008).

## Definition

The transmission of traits encoded in genes from parent to offspring.

## Introduction

Until the 1830s, heredity remained poorly understood. In 1858, one of the most significant developments in the study of hereditary processes was represented when the theory of natural selection was proposed by Charles Darwin and Alfred Wallace. However, our knowledge of heredity and modern understanding of inheritance of traits originates from the principles proposed by Gregor Mendel in 1865 who provided particular laws of inheritance for the passing of distinct traits from one generation to the next (Cobb 2006; Miko 2008a).

Heredity is biological processes in which particular characteristics are passed from parents to their offspring through the genes. The subject concerned with the study of heredity is known as genetics.

## Basis of Heredity

Genes are the building blocks of heredity which are composed of DNA and determine specific characteristics, such as height or hair color. DNA is a long polymer molecule that integrates four types of interchangeable bases (adenine, thymine, cytosine, and guanine) and encodes genetic information. In fact, the sequence of bases alongside a

certain DNA molecule specifies the genetic information. Mutations can modify DNA structures and genes which yield new alleles. Therefore, the new allele may affect the trait that is controlled by affected gene leading to change of the phenotype of the organism. In the nucleus, DNA molecule is packed many times around proteins called histones and forms nucleosomes. Then nucleosomes tightly coil up and create chromatin loops. The chromatin loops are then wrapped around each other and make thread-like structures called chromosome. Chromosomes are condensed structures within cells carrying genetic information in the form of genes. Human cells have 23 pairs of chromosomes; of these, 22 contain the non-sex chromosomes (autosomes) and the 23rd pair is the sex chromosome which determines gender. Females have two X chromosomes and males have one X and one Y chromosome. Therefore, females have two copies of every gene.

Genetic material is inherited from parents in the form of homologous chromosomes. Homologous chromosomes are chromosome pairs, each derived from one parent, having the same length, gene sequences, and centromere location.

Traits are observable characteristics that are passed down from parent to offspring. Some traits are inherited and others result from interactions with the environment. Traits are autosomal or sex-linked which are determined by the location of the alleles in the genome. Sex-linked traits are controlled by an allele which is found on the sex chromosomes, while autosomal traits are depended on the presence or absence of certain alleles located on non-sex chromosomes. Several traits are influenced by heredity including physical characteristic, intellectual capabilities, and emotional characteristics.

Simple creatures duplicate their genetic information and then splitting to form the same creature. More complex creatures produce gametes that carry half of the genetic information and then combine these to form new creatures. Therefore, the second generation will have diversity that they inherit from the first generation. Most of traits are influenced and controlled by multiple interacting genes and the environment (Berkowitz 1996).

## Gene Transmission in Mitosis

Mitosis and meiosis cell division transmit genetic material in very different ways. Mitosis division is the procedure of nuclear division that produces two identical cells (daughter cells) from a single cell and takes place in all types of somatic cells. The DNA is copied before cell mitosis resulting in two new cells each inheriting the DNA sequence in the nucleus. Therefore, each cell will receive the same number of chromosomes and identical genetic content as its original cell.

## Gene Transmission in Meiosis

Meiosis is a process that one diploid cell undergoes two cycles of cell division to produce four sex cells (gametes) with half the number of chromosomes as the parent cell. The resulting gametes have 23 new chromosomes (haploid) that represent distinct mixtures of the original maternal and paternal copies. During sexual reproduction, when the sperm and egg fuse by the process of fertilization, the number of chromosomes in the offspring is restored.

Crossing over or genetic recombination is a significant process that happens during meiosis resulting in new combinations of genes and increase genetic variability within a species and helps them to survive. Siblings with the same parents have some traits over others because they inherit a few genes from each parent instead of inherit identical DNA from one parent. In somatic reproduction, variation arises mainly from mutation in a DNA sequence. However, in sexual reproduction, variation arises from both mutation and recombination. Mutation creates the different versions of the same gene. Then during meiosis parental alleles are recombined. Owing to recombination, sexual reproduction yields more variation than somatic does (Miko 2008b).

## Mutation

Mutations, main cause of diversity among organisms, are changes that affect genetic sequence.

These changes can occur at many different levels, and based on their context or location they can be neutral, useful, or harmful. Mutations usually result in the development of new traits that are heritable or capable of being inherited. Since many mutations happen during the growth and development process, all cells in the body do not have identical genomes.

Mutagens are chemical or physical factors that increase the rate of mutation. Mutations are resulted from insertion or deletion errors during DNA replication or other types of damage to DNA. Generally, gene mutations are classified in two major types: germline mutations and somatic (acquired) mutations. Germline mutations are present in the germ cells and passed on offspring from a parent. On the other hand, somatic mutations are present only in somatic cells and usually caused by environmental factors, including UV radiation, chemicals, and viruses. However, these mutations cannot be passed on to the offspring. Most hereditary diseases are related to a mutation such as cystic fibrosis, sickle cell anemia, phenylketonuria, and color blindness (Loewe 2008).

## Genotype and Phenotype Relationship

Wilhelm Johannsen categorized the difference of genotype and phenotype in 1912. Genotype and phenotype are related concepts but have different meanings. The genotype is the set of genes in our DNA and inheritable genetic identity carried by all living organisms, which is responsible for a specific characteristic. Genotypes are either homozygous (two identical alleles) or heterozygous (different alleles). The phenotype is the visible expression of the gene information, combined with the environmental influence on an organism's appearance or behavior. In fact, genotype codes for the phenotype. Most phenotypes are influenced by both genotype and circumstances. Although the genotype is a major influencing factor in the development of phenotype, the phenotype arises from the complex interactions between genes and environment (Miko 2008a).

Genes are functional units of heritable material that are found within all living cells. Meanwhile

human cells carry two copies of each chromosome; they have two versions of each gene. Alleles are different versions of a gene and defined as either dominant or recessive.

The terms dominant and recessive are related to the inheritance patterns of particular characteristic and define how it is likely a particular phenotype pass from parent to offspring. The study of heritable traits helps scientists to determine which traits are dominant and are likely to be transferred from one parent to the next generation. These terms are useful in prediction of the probability of genetic disorders. Dominant alleles show their effect though individuals have one copy of the allele, which can come from just one parent. Therefore, for dominant trait you only need one copy of the alleles. For example, for having brown eyes you only need one copy of the “brown eye” allele. On the other hand, recessive trait only will be passed on if both parents possess it. An example of recessive trait is blue eyes, which can manifest in the offspring only if the individual has two copies of recessive alleles, one from each parent. Furthermore, once both alleles are dominant and expressed equally in offspring it is called codominance. The resulting trait is caused by both alleles. Indeed, an allele (from both parents) combines in the descendants and the offspring shows both phenotypes. For example, blood group AB is the result of codominance of the A and B dominant alleles (Peirson 2013).

## Natural Selection

The theory of natural selection, first developed by Charles Darwin, is regarded as one of the basic mechanisms of evolution. Natural selection is referred to a process in nature in which organisms possess certain genotypic characteristics that make them better adapted to their environment. Indeed, favored heritable traits increase an organism's chances of survival and reproduction and make them able to transmit and preserve their crucial genotypic potentials to their consequent generations (Endler 1986; Millstein 2002).

## Conclusion

Heredity is the biological process responsible for the transmission of heritable traits from parents to offspring via DNA. Heredity is a central component of evolutionary alteration, and variant characters highlight the complexity of understanding genetic impacts on phenotypes. Through heredity, differences within or between species can accumulate and increase the ability of individuals to survive by natural selection. Environmental elements can also interact with genetic information and resulting in even more genetic diversity.

### Heritability

## Definition

Heritability is defined as a statistical study of genetics that provides an estimation of the amount of variation in a phenotype of individuals within a population that is due to genetic variation (Wray and Visscher 2008). Thus, heritability estimates tell us what percentage or ratio of variation in a given trait or a disorder is due to genes versus the environment.

## Introduction

Varying phenotypes between individuals of a population are due to both environmental and genetic factors, along with the several interactions between the two. Heritability is a concept that describes how much of the variation in a trait is due to variation in genetic factors. This term is most often used in reference to the similarity between parents and their offspring. In this context, high heritability suggests a strong

resemblance between parents and offspring with regard to a specific trait, while low heritability indicates a low level of resemblance. There are many common misconceptions on the exact meaning and interpretation of heritability. Heritability is not the ratio or percentage of a phenotype that is genetic, but rather, the ratio or percentage of phenotypic variance that is due to genetic factors.

The value of the heritability estimate lies between 0.0 and 1.0, where 0.0 indicates that genetics are not a contributing factor at all and 1.0 indicates that genetics are the only contributing factor for the trait in question. For example, the heritability estimate for any particular disorder is 0.5, which means that half of the variation seen in that disorder across a population is due to genes (biologically inherited) and half is due to the environment (school, work, home life, etc.). In other words, it can be said that genes and environment both are contributing equally to this disorder.

## Heritability Types: Broad-Sense Heritability and Narrow-Sense Heritability

Broad-sense heritability ( $H^2$ ) reflects all possible phenotypic variance due to the genotype, i.e.,  $H^2 = V_G$  (Genotypic Variance) /  $V_P$  (Phenotypic Variance). Phenotypic Variance ( $V_P$ ) is due to the sum of three components: environmental variance ( $V_E$ ), genotypic variance ( $V_G$ ), and variance resulting from the interaction of environment and genotype ( $V_{GE}$ ), i.e.,  $V_P = V_E + V_G + V_{GE}$ . However, Genotypic Variance ( $V_G$ ) can be further divided into additive, dominance, and epistatic variances. An  $H^2$  value that approaches 1.0 indicates that the environmental conditions have had little impact on phenotypic variance. An  $H^2$  value close to 0.0 indicates that environment has been almost solely responsible for the observed phenotypic variations.

Narrow-sense heritability ( $h^2$ ) includes only that proportion of genetic variation that is due to additive genetic values ( $V_A$ ), i.e.,  $h^2 = V_A/V_P$ . Additive genetic variation ( $V_A$ ) refers to genetic effects where each allele at each of the many genes that codes for a trait has a small effect on

the phenotype and the phenotype depends on the sum of the effects of all of these alleles with each allele contributing equally.

## Methods for Estimating Heritability

Genetic gain or selection response (R) can be calculated by the product of heritability ( $h^2$ ) and the selection differential (S). Heritability estimates generally depend on the assumptions of large random mating populations in the absence of mutation, migration, selection, and genetic drift. Most methods for estimating heritability are available for diploids with normal meiosis. Sex-specific differences in recombination should also be taken into account while estimating heritability (Sakamoto et al. 2000).

Generally, there are two types of methods used for heritability estimation. The first method makes use of regression and correlation to estimate heritability whereas the second method involves use of analysis of variance (ANOVA) and estimation of variance components to estimate heritability. The different methods for estimating heritability can be explained in the following ways (Friars and Smith 2010):

### (i) Regression Between Parents and Offspring

This method estimates the amount of the transmission of any particular trait from parent to offspring and uses the following formula:

$$y = a + bx$$

where x, y = mean values of the trait for the parents and offspring, respectively,

a = intercept, and

b = regression coefficient.

The heritability will be equal to the regression coefficient, i.e.,  $h^2 = b$ , when the mean values of a trait from both parents will be used; however, when the offspring will be compared with just one parent, then the heritability will be  $h^2 = 2b$ .

### (ii) Hierarchical Matings

This is also known as North Carolina mating design I. This method estimates the source of variation in the population and uses the following formula:

$$Y_{ijk} = \mu + S_i + D_{ij} + e_{ijk};$$

where  $Y_{ijk}$  = trait measurement on the  $k^{\text{th}}$  progeny of the  $j^{\text{th}}$  dam (female parent) mated to the  $i^{\text{th}}$  sire (male parent),

$\mu$  = overall mean of the population,

$S_i$  = effect of the  $i^{\text{th}}$  sire,

$D_{ij}$  = effect of the  $j^{\text{th}}$  dam mated to the  $i^{\text{th}}$  sire, and

$e_{ijk}$  = environmental plus genetic segregation effect on the  $k^{\text{th}}$  progeny of the  $j^{\text{th}}$  dam mated to the  $i^{\text{th}}$  sire.

The heritability in this case can be calculated from the sire component ( $h^2_S$ ), the dam component ( $h^2_D$ ), and the sire and dam component ( $h^2_{S+D}$ ), whose formulas are as follows:

$$h^2_S = 4 \sigma^2_S / \sigma^2_S + \sigma^2_D + \sigma^2_e$$

$$h^2_D = 4 \sigma^2_D / \sigma^2_S + \sigma^2_D + \sigma^2_e$$

$$h^2_{S+D} = 2(\sigma^2_S + \sigma^2_D) / \sigma^2_S + \sigma^2_D + \sigma^2_e$$

where

$\sigma^2_S$  is the sire component of variance,

$\sigma^2_D$  is the dam component of variance, and

$\sigma^2_e$  is the environmental plus genetic segregation component of variance.

### (iii) Factorial Matings

This is also known as North Carolina mating design II. In this method, sets of matings (in which sires and dams of each strain are mated to each other) are used for partitions of variance components, where the theoretical expectations of

| Variance component | $\sigma^2_A$ | $\sigma^2_D$ | $\sigma^2_{AA}$ | $\sigma^2_{AD}$ | $\sigma^2_{DD}$ | $\sigma^2_{Ec}$ | $\sigma^2_{EG}$ | $\sigma^2_M$ |
|--------------------|--------------|--------------|-----------------|-----------------|-----------------|-----------------|-----------------|--------------|
| Between families   | 1/2          | 1/4          | 1/4             | 1/8             | 1/16            | 1               | 0               | 1            |
| Within families    | 1/2          | 3/4          | 3/4             | 7/8             | 15/16           | 0               | 1               | 0            |

additive and nonadditive effects are as follows (McKay et al. 1986):

- $\sigma^2_A$  = variance due to additive genetic effects
- $\sigma^2_D$  = variance due to dominance
- $\sigma^2_{AA}, \sigma^2_{AD}, \sigma^2_{DD}$  = variance due to epistatic interactions of additive-additive, additive-dominance, and dominance-dominance types, respectively
- $\sigma^2_{Ec}$  = variance due to environmental effects between tanks
- $\sigma^2_{EG}$  = other environmental effects not due to tank effects
- $\sigma^2_M$  = variance due to maternal effects

(iv) **Breeding Values**

In this method, the selection criteria for the prediction of breeding values in large data sets are based on best linear unbiased prediction (BLUP) of additive genetic effects. Another most commonly used method for the estimation of variance components of mixed linear models in animal breeding is restricted maximum likelihood (REML) method (Hofer 1998).

(v) **Inbred Lines**

In this method, the use of variance between and within inbred lines can be used to estimate genetic variance and heritability using the following formula:

$$h^2_t = h^2_o (1 - F_t) / (1 - h^2_o F_t);$$

where

$h^2_o$  is the heritability in the base population, and  $h^2_t$  and  $F_t$  are the heritability and inbreeding coefficients at time represented by generations  $t$ .

(vi) **Linear Heritability Estimates**

This method is based on selection of potential parents for which estimates of average genotypic and phenotypic values are obtained from a pedigree population (Abplanalp 1961). In this method, a regression of genotypic on phenotypic values is estimated from a straight line joined through the points representing the mean genotype and phenotype of selected parents on one axis and the population mean genotype and phenotype on the other.

(vii) **Clonal Lines**

In this method, firstly mitotic gynogenetic diploids were produced and reared in a common environment, and then the lines were identified using DNA fingerprinting and after that human twin model were employed to observe the separated genetic and environmental variances (Taniguchi et al. 1996).

(viii) **Discrete Traits**

In this method, heritability can be estimated from an underlying continuous scale using techniques, which provide a quantification of multiple gene effects (Robertson and Lerner 1949).

(ix) **Animal Model**

In this method, an animal model is used for heritability estimate by estimating its breeding value through the information of animal's records, its parents, and its progeny details. This method is based on the condition that provided pedigree information of the animal is accurate and complete.

**Conclusion**

The heritability plays an important role in the phenotypic individual differences. Statistical definition of heritability can be given as the ratio of

phenotypic variance derivable to the genetic variance. This ratio always ranges from 0 to 1 depending upon whether genes don't contribute at all or contribute fully for individual phenotypic differences. For example, nearly all heritability estimates lie in the moderate range of .30–.60 for human behavior. Knowledge of this statistical parameter helps breeders in choosing if it is more effective to enhance qualities through management or through selection of a particular livestock/crop/species.

## Definition

Heritability of behavior is a quantitative estimate of how much proportion of a variation in an observed behavioral trait can be attributed to the genetic factors. A variation in an observed behavioral trait is assessed using population statistics.

## Introduction

The postulate that animal behavior has a genetic basis is now well supported by scientific literature, and the determination of heritability has been an important measure in current quantitative behavioral genetics. Nature versus nurture (or gene versus environment) contribution in expression of a trait (i.e., phenotype) has been a longtime conflict, leaving scholars either denying contributions by one of

these or claiming dominance over each other. Environment refers to anything other than genotype, to which an individual is exposed and which may influence expression of a trait. Psychologist Eric Turkheimer proposed three laws of heritability which got wide acceptance among the scholars of behavioral studies. The first law says all human behavioral traits are heritable. The second law says the effect of shared family environment is less than genes. The third law states that a substantial proportion of variation in complex behavioral traits is not explained either by environment or genes (Turkheimer 2000). These laws are in stark contrast to the primitive views regarding biological basis of behavior which had given sole importance to the environment. Although now enough literature is available which provides scientific basis for the heritability estimation in behavior, the evidence also supports inclusion of the counter view (Flynn 2001). Conceptually, heritability doesn't ensure that any percentage of the said behavioral trait will be solely decided by genes. Current view is that although genes may have an essential role, animal behavior is decided by the intricately multifaceted interplay of the contributing factors and not by any single factor in isolation (Johnson 2007).

For individuals sharing the similar environment, genes may have a greater say in deciding observed variance in a trait; in turn, for the individuals who share a common genotype, any variance may be attributed to the environment. Also, a genetic influence on behavior can be amplified or buffered by environmental conditioning, and the environments which are not shared by others and are unique to the individuals may have specific impacts on the behavior of exposed individuals.

### **Heritability: Concepts, Mechanisms, and Misconceptions**

Heritability is nearly a century-old concept introduced by Sewall Wright and Ronald Fisher which provides estimate for the contribution of the nature (i.e., genes) for phenotype variations in nature versus nurture (i.e., environment) conflict and can be expressed in proportions (between the variation in a phenotype due to genes and total

variations). Although in literary sense heritability signifies resemblance of traits between parents and offspring, in scientific use, it is a statistical parameter. Conventionally heritability is symbolized as " $h^2$ " (explained by Sewall Wright's path coefficient model, he used " $h$ " for heredity and square of this presented correlation or regression between phenotype and genotype variances) (Visscher et al. 2008). The numerical value of heritability ranges from 0 to 1 (or can be expressed in percentage 0–100), signifying no role to absolute role of genes for a phenotype/trait. Heritability is specific to the population and environment and a selective parameter to measure genetic influence on the variance for a trait at population level rather than in single individuals. Heritability can be described as narrow-sense heritability ( $h^2$ , what we conventionally call as heritability), which accounts specifically additive effects of the contributory genes, and broad-sense heritability ( $H^2$ ) which includes all genetic factors.

Genetic factors other than additive gene effects may be gene-gene interactions (epistasis) and gene-environment interaction. Epistasis implies that when more than one genes are influencing the same trait, their combined effects may not be additive but follow complex interactions resulting in phenotypic outcomes. The epistatic mechanism involves inter-allelic interactions between loci for more than one gene and this way may mask or modify the expression of some genes manifesting invariant phenotypes. Inter-allelic interaction within loci for the individual genes may result in dominant and recessive phenotypes for a particular trait (Phillips 2008).

Mechanisms operating in gene-environment interactions are not comprehensively known yet, but gene expression changes mediated by transcription factors, micro-RNA-mediated gene silencing (Geeleher et al. 2012), and epigenetics are some known mechanism mediating gene-environment interactions. Epigenetics registers environmental influences on the base or chromatin structure of a chromosome by specific mechanisms without bringing any change in the base-pair sequence, by this influencing the expression of genes (Zhang and Meaney 2010). Trans-generational epigenetics (Jensen 2013) has been

considered as a plausible explanation for missing heritability (for the traits for which no genetic markers could be found in genome-wide association studies (GWAS) to support its estimated heritability) (Marian 2012). Although most of the epigenetic changes are routinely erased from the genes by epigenetic reprogramming during gametogenesis, challenging its significant contribution to the heritability of traits, a recent research evidence suggests some epigenetic changes implicated in specific behavioral aspects may escape the erasure and may be inherited to the offspring, which may be crucial for expression of specific behavioral traits, indicating a probable role of epigenetic mechanisms in heritability of behavior (Hackett et al. 2013).

Heritability is traditionally estimated as the correlation of phenotype variance between offspring and parents, between full and half siblings, or difference in correlation of monozygotic and dizygotic twin pairs. Broad-sense heritability which includes all genetic factors can be defined as the proportion of genotypic value ( $V_G$ , combined effect of all inter-allelic interactions including dominance and epistasis) to phenotypic variance ( $V_P$ ),  $H^2 = V_G/V_P$ . Narrow-sense heritability only includes the additive effect of genes ( $V_A$ ) and presented as  $h^2 = V_A/V_P$ .

In artificial selection experiments (selective breeding of the organisms to get desirable traits), heritability can be estimated from the ratio of the observed selection response ( $R$ ) to the observed selection differential ( $S$ ) which is also known as breeder's equation heritability ( $H^2 = R/S$ ). Observed selection response ( $R$ ) has been a post-selection change in the population mean for a trait, and observed selection differential ( $S$ ) is the difference between the mean of the parents and that of the original population under observation for a trait.

A novel method of heritability estimation has been suggested by comparing the percentage of genetic similarity between siblings (derived from the genome-wide expression of genetic markers) with phenotypic variance (Visscher et al. 2006). Another novel method for heritability estimation implied DNA fingerprint markers and maximum likelihood calculation without using any prior

information on the relatedness of the subjects (Mousseau et al. 1998).

An interesting observation about heritability is that it may change with time and age caused by changes in genetic variations in a population. Genetic variations are known to change with time and age in response to new environmental conditions which may alter allelic frequencies or may induce new mutations in the genome (Visscher et al. 2008).

## Misconceptions

Heritability may be misunderstood as the inheritance of a trait (which is definitely an exclusive function of genes) a common misconception among beginners in population genetics. Contrary, heritability is a statistical estimate which doesn't give any information about the genetic structure of the individual. It rather gives an indication that genes may be attributed for certain fraction of a variation in a trait at the level of population. Heritability estimate is also specific to each population, and nontransferable, but surprisingly it has been almost conserved across populations and species.

Another common misconception regarding the definition of heritability to take care is it is not the proportion of phenotype but that of phenotype variation explained by genetic factors which constitute heritability (Visscher et al. 2008).

## Study Designs for Estimating Heritability of Behavior

### Twin Studies

Classical twin studies have been employed mostly for estimating heritability. The monozygotic twins (identical twins who share hundred percent of genes) when compared with dizygotic twins (who share, on average, only 50% of genes) if have been exposed to same kind of environments, a deviation of behavior can be attributed to the genes (because environment has been the same for both comparing groups).

### Adoption Studies

This study design gives an indication of the role of the environment. When siblings of the similar genetic background (especially, monozygotic or identical twins) are reared up in a different family environment, as genes are similar, any deviation in a behavioral trait may be attributed more to the environment. This study design can be also used for the siblings who will have a certain level of genetic similarity which can be assessed by using DNA markers (Visscher et al. 2006); if raised in a different family environment, the heritability of a behavioral trait can be estimated from phenotype variation versus shared genes plot.

### Children of Twins

Children of the twins can be followed for the continuation of the deviant behavior in changing rearing-up environment which can be attributed to the genes, and appearance of a new deviant behavior which parents didn't bear can be attributed to the environment.

### Molecular Genetic Designs

**Genome-wide association studies (GWAS):** Searching for SNPs (single-nucleotide polymorphs) in the whole genome can be attributed for the noted variance in the behavior. Nowadays, this study design is commonly used for estimating heritability, but an overly emphasized use of statistics complicates the whole issue, and slight variation of statistical parameter yields magnificent changes in GWAS results. This is the reason that GWAS studies are seen with skepticism.

**Candidate genes:** Several candidate genes have been tagged with various behavioral aspects (e.g., MAOA gene to antisocial behavior, dopamine receptors DRD2 and DRD4 to aggression and antisocial behavior, serotonin transporter 5HTTLPR for depression, SLC6-a noradrenalin polymorph to attention deficit hyperactivity disorder (ADHD), and GABRA2-a GABA polymorph to childhood conduct disorder and substance abuse

in adults (Kretschmer and Delisi 2016)). Many other candidate genes have also been reported which may influence animal behavior, but never a major causal relationship has been proved for any such gene. For the details on candidate genes implicated in behavior, interested readers may consult referred source (Flint and Munafò 2013).

### Developmental Models

Developmental models are based on the concept that heritability changes over age course of individuals as they grow. If a child is followed over the course of life for continuity of a particular behavioral trait, a change may be attributed to the changing environment or to the experience the child has gained while growing up, but a gene-environment interaction or influence of the genes in selection or rejection of the environmental conditions or adjustment of the individual to the faced environment may not be denied.

### Empirical Evidence for Heritability of Behavior

Heritability estimation through scientifically designed studies has been done for almost each aspect of the behavior; majority of the studies focused on personality traits (Bouchard 2004), intelligence (Devlin et al. 1997), attitude (Olson et al. 2001), and cooperative (Cesarini et al. 2008) and antisocial behavior (Grove et al. 1990). Heritability of cognitive traits such as memory, learning, and fear has been also studied (Croston et al. 2015). Advancement in genetic research has established the imperative role of the cascade of genes in behavioral complexity (Plomin et al. 1994), providing an empirical basis to the heritability of behavior. Heritability estimate ranges between 30% and 60% for various aspects of animal behavior (see "Heritability: Introduction"/Colorado University-Psychology). Heritability of personality traits alone in average has been estimated as 40% (Vukasović and Bratko 2015).

Certainly, classical twin studies have been most commonly used for this purpose as this study design provides unique opportunity to deduce conclusion on gene-environment conflict, as we discussed above. Although there have been conflicting views on the heritability of behavioral traits, taking the example of intelligence for which determinative role of nature (Plomin and Deary 2015) or nurture (Kendler et al. 2015) has never been resolved and research evidence appear in favor of both. If we consider intelligence that is measured by the intelligence tests and represented by IQ, sufficient evidence regarding heritability for this trait is now available (Snickers et al. 2017). Uniquely, heritability estimates for intelligence have been shown to be also influenced by assortative mating (a tendency of individuals to mate with a person of similar traits) and cultural transmission (transmission of environmental factors that are related to a trait and passed from the parents to offspring and are shared between siblings) further perplexing the nature versus nurture debate (Vinkhuyzen et al. 2012).

### Gene-Environment Interplay for Behavioral Traits

**Gene-environment interaction:** Not separately genes or environment but the interactions of both may be the guiding element for variance in behavior.

**Gene-environment correlation:** Genes may be deciding the coming environment an individual will face, for example, an anxious child may prefer to keep away from the challenging environment.

### Fallacy of Classical Twin-Based Studies Estimating Heritability of Behavior

The twin-based study designs for estimating heritability had been in question for relying on the assumption regarding the environment (Moore and Shenk 2017). In the classical twin-based studies, monozygotic and dizygotic twins are assumed

to have been exposed to similar environments, and heritability estimates are based on that, but what scholars suggest is, unknowingly, parents might provide monozygotic twins an environment more similar than that given to dizygotic twins due to the inherent behavioral similarities and close preferences for the things and surroundings in the siblings of monozygotic twins induced by identical genes (Moore and Shenk 2017). A breach in the assumed similarity of the environments for the monozygotic and dizygotic twins will definitely influence the heritability estimates to some extent, although it doesn't nullify the contribution of genes for the induced variation in a trait. An assumption-free method of heritability estimation in full siblings is based on the percentage of gene sharing between them as a function of variation in a trait, reported by Visscher et al. (2006), but its application in behavior quantitative genetics is still not confirmed.

### Applied Implications

Heritability estimation can be used for predicting the risk of the parent to offspring continuance of the behavioral traits or disorders. Heritability estimation of behavioral traits has been often used to provide justification for the logics regarding an indispensable role of genes in deciding the behavior of an individual, which may be a deciding factor in formulating policies for punishments or rehabilitation for a deviant behavior in adult or children (Joseph 2001). A behavioral trait which depends more on the environment than genes would suggest environmental modification may improve a deviant behavior and a higher heritability vice versa may indicate stubbornness for any improvement. But alternative view has been given for this, even in a case of high heritability; environmental modifications may improve individual's behavior through gene-environment interplay (Kendler et al. 2015).

Heritability also explains why individuals (even in a close community or family or twins) are so different in behavior (due to their unique genetic makeup) and helps understand a necessary social

value for the diverse behavioral attributes among individuals which has to care while drafting social policies (Manski 2011). It also reminds us that everything wanted can't be inserted or vice versa everything unwanted can't be erased in the society through modification of the environment only, and stubbornness of genes for a radical change and their complex interplay with the environment have not to be ignored. Heritability estimate may also be used for predicting continuance of behavioral or related disease traits in offspring in case of the selective mating of the parents.

## Heritable Factors

### ► Polygeny

## Hermann von Helmholtz

Roger K. Thomas

Department of Psychology, University of Georgia, Athens, GA, USA

Hermann von Helmholtz 1821–1894

## Preface

This entry is based extensively on three biographies of Helmholtz, Cahan (2018), Koenigsberger (1902/1965), and Muelders (2001/2010), and on Boring (1950) for his emphasis on Helmholtz's relevance for Psychology. These four references overlap considerably on the facts of Helmholtz's life and many accomplishments relevant to physics, physiology, and psychology. Therefore, source citations for each and every fact presented here from these four sources will be limited generally to quotations or matters unique to a source. Other references are cited as needed to document particular points of interest.

## Pre-University Years

Hermann Ludwig Ferdinand Helmholtz was born on August 31, 1821, in Potsdam, Germany. His father August Ferdinand Helmholtz was a teacher at the Potsdam Gymnasium (high school) and his mother (née Caroline Penne) was a remote descendent of William Penn, Founder of Pennsylvania (1681).

Helmholtz grew up in an upper-middle class home but enjoyed cultural advantages above his family's station, as his father was a teacher and a military veteran and his mother was the daughter of a military officer. Helmholtz learned and enjoyed playing piano. He took his piano with him to college and said later that it was beneficial when he wrote a treatise on the psychology of music.

In high school, Helmholtz followed a classical curriculum that included physics, mathematics, Latin, Greek, French, English, Italian, Hebrew, and rudiments of Arabic. He was said to be a good but not exceptional student.

## University Education and Service as Physician-Surgeon in Prussian Army

Helmholtz's preference for advanced study in physics and mathematics was deemed impractical financially, so in autumn of 1838, he passed the entrance exam and enrolled in the Prussian Army's medical school, the Friedrich-Wilhelm Medicosurgical Institute in Berlin. The Medicosurgical Institute was affiliated with the University of Berlin's Medical Faculty. Room and instruction were free to all students, but Helmholtz had additional financial needs that compelled him to commit to 8 years' service upon graduation as a physician-surgeon in the Prussian Army.

Helmholtz was most impressed by Johannes Müller's lectures in physiology at the University of Berlin. Müller was Germany's most renowned physiologist based upon (among other accomplishments) having completed his 8-volume *Handbuch der Physiologie des Menschen* in 1840 (see Boring 1950, pp. 34–35 for brief summaries of each of the eight volumes or see “Müller, Johannes Peter” in this Encyclopedia).

Müller supervised Helmholtz's doctoral thesis. Helmholtz received his diploma on November 2, 1842.

Helmholtz became friends with some of Müller's students and assistants, including Emil du Bois-Reymond, Ernst Wilhelm von Brücke, and Carl Ludwig. du Bois-Reymond became well known at the University of Berlin for his research in muscle electrophysiology. Brücke became an eminent physiologist at the University of Vienna where Sigmund Freud was his student for 5 years; Freud described Brücke as his greatest teacher. Carl Ludwig would become Chair of Physiology at the University of Leipzig where he influenced Wilhelm Wundt, founder of Experimental Psychology, and Ivan Pavlov, discoverer of the conditioned reflex.

Müller believed in vitalism (i.e., a “life force” in biology that could not be reduced to chemistry and physics). du Bois-Reymond, Brücke, Ludwig, and Helmholtz strongly opposed vitalism. du Bois-Reymond and Brücke pledged to compel the truth that “No other forces than common physical chemical ones are active within the organism” (Boring 1950, p. 708). Surely Ludwig and Helmholtz shared this view, but perhaps they were absent when the pledge was made. Below we shall see that two achievements by Helmholtz essentially demolished vitalism, although some biologists persisted in believing in vitalism decades later (see Guyer 1931, pp. 22–23).

After completing his dissertation in 1842, Helmholtz began to intern at the Charité Hospital, a teaching hospital in Berlin, and subsequently qualified to become a physician-surgeon. In October 1843, Helmholtz began his service as a Prussian Army physician. During his military service years, Helmholtz made two of his most important contributions, both of which refuted vitalism.

In 1847 (age 28), and based upon many experiments in physiology, especially, metabolism, Helmholtz formulated the law of conservation of energy which he published as *Ueber die Erhaltung der Kraft* (On the Conservation of Force). Cahan (2018, p. 151) summarized the law as follows:

Nature as a whole contained a store of force . . . that could be neither Increased nor decreased; its total quantity was “eternal and unchangeable like the quantity of matter.”

A passage from its philosophical introduction (approximately 1 3/4 pages) may be seen in English translation in Fulton and Wilson (1966, pp. 22–24).

## Determining the Speed of Neural Conduction

On September 30, 1848, Helmholtz was released from his last 3 years of military service. He also abandoned the practice of medicine. On May 19, 1849, he was appointed Extraordinary Professor of Physiology at the University of Königsberg.

Johannes Müller believed that the speed of neural conduction was on the order of the speed of light and that it would never be measured. In his *Handbuch*, Müller cited sources for three possible speeds, the highest being 60 times the speed of light (Boring 1950, p. 41). This, presumably, supernatural speed for neural transmission and Müller’s belief that it could never be measured importantly influenced his belief in a “life force” (i.e., vitalism). On January 15, 1850, approximately 6 years after Müller’s prediction that the speed of nerve conduction was immeasurable, Helmholtz sent to du Bois-Reymond a short report: “On the Rate of Transmission of Excitation in Nerve.” Helmholtz also sent the report to Müller. Using a frog nerve-muscle preparation, Helmholtz had determined the speed of neural transmission to be on the order of 90 ft/s. Later, Helmholtz would find comparable results using sensory nerves.

## Vitalism’s Parallel in Psychology

In psychological science, most researchers show no hesitation in attributing “emergent properties” to phenomena being studied; such activity is now referred to as “emergentism.” The readiest example of emergentism is the reification of fictional concepts, for example, “stress caused her illness.” “Stress” can be neither a cause nor an effect (e.g., his impending final examination in calculus cause him “stress”) because “stress” is fictional in the

sense of having no material (i.e., chemical-physical) reference, a concept that merely names the condition it is purported to cause. It is far too common to reify such concepts in psychological research, and many examples could be cited easily. See related discussion of emergentism in animal cognition and the reification of concepts in the “► [Morgan’s Canon](#)” and “Müller, Johannes Peter” entries in this *Encyclopedia*.

## Helmholtz’s Other Academic Positions

After his years at the University of Königsberg, 1849–1855, Helmholtz relocated to the University of Bonn, 1855–1858, where he was Professor of Physiology and Anatomy. From 1858–1871, Helmholtz was Professor of Physiology at the University of Heidelberg, and from 1871 to 1888 he was Professor of Physics at the University of Berlin. At the time he was appointed to them, the Professorships in Physiology at Heidelberg and in Physics at Berlin were Germany’s most prestigious positions in those respective fields. Finally, Helmholtz served as Rector (President) of the Imperial Physico-Technical Institute in Charlottenburg from 1888 until his death in 1894.

## Additional Accomplishments by Helmholtz

Helmholtz had so many scientific accomplishments that only a few can be included here. It is reasonable to suggest that, had the Nobel prize existed before Helmholtz died in 1894 (the first Nobel Prizes were awarded in 1901), he likely would have qualified for at least two, one for having developed the law of conservation of energy and one for measuring the speed of neural transmission, both of which were supported by numerous experiments in his laboratory. Two other areas of accomplishment will be discussed here, namely, Helmholtz’s theoretical and experimental work in vision and audition, two fields to which his important contributions might also have qualified him for Nobel prizes.

### Helmholtz's Research in Vision

Perhaps, the first accomplishment to be mentioned is his 3-volume, *Handbuch der Physiologischen Optik: Vol. 1* (1856), *Vol. 2*, (1860), *Vol. 3* (1866) about which Boring in 1950 wrote, "It remains today a gospel in its field" (p. 302). The three volumes spanned physics, physiology, and psychology.

**Invention of the ophthalmoscope.** Helmholtz is recognized for inventing the ophthalmoscope, an instrument that enabled critical advancement in the study of visual optics. Helmholtz noted that Ernst Brücke had come within "a hair's breadth of the invention of the ophthalmoscope" (Helmholtz quoted in Cahan 2018, p. 96). Cahan (2018, p. 96) added:

It was only Brücke's failure to inquire about the return path followed by the light sent to the observed eye and how an optical image is formed in the observer's receiving eye that prevented him (in principle) from becoming the ophthalmoscope's inventor.

Helmholtz commented further that there were five to ten other German scientists:

... who doubtless would have performed in a completely logical way exactly the same as I if they had been put before the same tasks and under the same conditions. (Helmholtz quoted in Cahan 2018, p. 96)

It may be of interest to note that one of Helmholtz's primary motivations for inventing the ophthalmoscope was that he wanted a way to demonstrate the anatomy of the retina to his students.

Helmholtz formally published his invention of the ophthalmoscope in 1851. It was a handheld instrument designed to enable a physician or researcher to view the retina with focused illumination from the instrument and, in Helmholtz's time, with 20 times magnification. It remains an important instrument in the ophthalmologist's armamentarium, although many improvements have been made since Helmholtz's was introduced.

Next, Helmholtz turned his interest to the study of the accommodation of the lens of the eye and that led to his invention of the ophthalmometer

(1852) to calculate the curvatures of the cornea and lens from measurements of the sizes of images reflected on their surfaces.

### Color Vision

In 1801, British physicist Thomas Young lectured before the Royal Society of London "On the Theory of Light and Colours." The lecture was published as Young (1802). Drawing heavily on Isaac Newton and others, Young argued that sensitive points in the retina consisted of particles that undulate (Young preferred "undulate" to Newton's "vibrate") to provide the different sensations of color. For Young, red, yellow, and blue were primary, and other colors resulted from resonant undulations with the primaries.

Helmholtz rejected most of Young's theoretical foundations, but he embraced the general concept of Young's trichromatic theory of color vision. Helmholtz's contributions to the theory of color vision led others to label it the "Young-Helmholtz trichromatic theory of color vision." Young had not known of the cells of the retina, but Helmholtz (*Handbook of Physiological Optics Vol. 1*, 1856) distinguished among nerve fibers, ganglion cells, and rods and cones in the retina. However, the functional difference between rods and cones was determined later (1866) by Max Schultz who was Helmholtz's successor at the University of Bonn.

Through his psychophysical research, Helmholtz decided that cones reacted differently to different wavelengths of light, and he proposed three types of cones: (a) short-wavelength-preferring cones, blue; (b) middle-wavelength-preferring cones, green; and (c) long-wavelength-preferring cones, red. Technology was not yet sufficient to determine how the cones reacted differently to wavelength of light as measured with a diffraction grating. That would come nearly a century later with the identification of three types of cones containing chemicals within that varied in the range and peak wavelengths of light to which they best reacted, namely, cyanolabe (cyanopsin) for sensitivity to blue, chlorolabe (chloropsin) for sensitivity to green, and erythrolabe (erythopsin) for

sensitivity to red. It was a century later that George Wald was awarded the Nobel Prize in 1966 for his research on the absorption spectra of the photopigments in the rods and cones of the retina.

Helmholtz and others studying color vision relied almost exclusively on human experimentation with psychophysical data (biochemical and electrophysiological data were still far into the future). Ewald Hering reported results that the Young-Helmholtz trichromatic theory could not explain, and Hering proposed an opponent-process theory of color vision that could account for his psychophysical research findings.

**Christine Ladd-Franklin (1847–1930) and Helmholtz.** Ladd-Franklin's name does not appear in the three Helmholtz biographies used here, but she may have been the only American (certainly the only American woman) to spend time in Helmholtz's laboratory and in Ewald Hering's laboratory to study color vision. This occurred when she accompanied her husband, Fabian Franklin, a mathematician, on his sabbatical from Johns Hopkins University to Germany in 1891–1892. Ladd-Franklin had earned a PhD in mathematics and logic at Johns Hopkins in 1882. However, women were not recognized formally, and she did not receive her doctorate until 1926. After her research experiences in both Helmholtz's and Hering's laboratories, Ladd-Franklin became a self-identified psychologist.

Ladd-Franklin developed a theory of color vision intended to account for both Helmholtz's trichromatic and Hering's opponent-process theories and to supersede them (Kargon 2014). Ladd-Franklin's theory was first presented at the International Congress of Psychology in London (1892) in a session on color vision. That evening, Helmholtz was part of a private discussion where he spoke disparagingly of one of the contributions (not Ladd-Franklin's). Someone asked Helmholtz what he thought of Dr. Ladd-Franklin's color theory. Helmholtz replied, "Ach, Fran Franklin, die versteht die Sache" (*Oh, Fran Franklin, she understands the matter*, quoted by an unidentified writer in Ladd-Franklin 1929, p. 148). This author

has been unable to find a definition for "Fran" in German. There may have been a typographical error, and "Frau," "Mrs." in German, may have been intended.

### Helmholtz's Research in Audition

Helmholtz's research on phenomena associated with sound and hearing overlapped his research on light and vision. His single volume about hearing, *Die Lehre von den Toneempfindungen als physiologische Grundlage für die Theorie der Musik* (*On the Sensations of Tone as a Physiological Basis for the Theory of Music*), was published in 1863. It presented a "resonance-place theory" for how the ear processes sound; that is, he assumed that places along the basilar membrane of the cochlea resonated differently to frequencies of sound somewhat like the strings of a piano. Helmholtz's knowledge of the anatomy and physiology of the function of the cochlea did not have the benefit of more advanced technology later used by Georg von Békésy who received the Nobel Prize in 1961 for his research showing the vital role of the basilar and tectorial membranes and the hair cells of the cochlea in auditory processing of different sound frequencies. However, in von Békésy's Nobel address, he stated:

For me the most stimulating book on hearing was Helmholtz's *Die Lehre von den Toneempfindungen* . . . Helmholtz's method of viewing physiology and psychology in physical terms is today just as fresh as the day it was written. (von Békésy quoted in Muelders 2010, p. 154)

### Three of Helmholtz's Most Notable Protégés

Helmholtz had many notable protégés in physics, physiology, and psychology, but the three considered here were clearly among the most outstanding.

#### Physics

**Heinrich Rudolph Hertz (1857–1894).** Hertz was a devoted student perceived apparently by

Helmholtz to be a rising star, and Helmholtz was a devoted mentor. Hertz provided some insight regarding social interactions with Helmholtz. On one occasion Helmholtz and his wife Anna invited Hertz to tea. Anna was the easier conversationalist. Hertz described Helmholtz as:

... very charming ... but he speaks in such a slow and measured manner that, for me at least, it's impossible to keep one's attention on him, except when it's a matter of things in which every word must be weighed. Then, however, the conversation stops, since I don't want to put my opinion up against him. (Hertz quoted in Cahan 2018, p. 605)

Hertz was often invited to social events at the Helmholtz's, and, as time passed, such events became much more relaxed for Hertz.

As a mentor, Helmholtz supported Hertz's research fully, offering suggestions and guidance when useful but allowing Hertz the freedom to work as he preferred. Helmholtz saw to it that Hertz's research was well published and promoted. Related to Hertz's future accomplishments, Helmholtz was the most energetic German scientist in bringing James Clerk Maxwell's theoretical work on electromagnetism from Scotland to the Continent. Helmholtz arranged to have Maxwell's *Treatise on Electricity and Magnetism* (1873) translated into German, and Helmholtz encouraged Hertz to bring experimental proof to Maxwell's theory. After some strong but preliminary work on proving Maxwell's theory, in 1888 Hertz hesitantly asked Helmholtz's assistance in publishing his latest work in *Sitzungsberichte*, which was the publication for the proceedings of the Prussian Academy of Sciences:

Yet the work in question was Hertz's epochal experimental proof of the identity of electromagnetic and light waves, a work that Helmholtz called "absolutely genius." Helmholtz asked du Bois-Reymond to rush Hertz's manuscript into print in the academy's *Sitzungsberichte*; it appeared soon thereafter. (Cahan 2018, p. 609)

Hertz died relatively young at age 36, a result of surgeries associated with severe migraines that led to infection.

In 1930, in honor of Heinrich Hertz, the unit *hertz* (Hz) was established by the International

Electrotechnical Commission as the standard unit for *frequency*, that is, the number of times that a cyclical event occurs per unit of time, i.e., cycles per second (cps). In 1960, the unit, Hz, was adopted by the General Conference on Weights and Measures, and although acceptance of Hz to replace cps was slow initially, by 1970 Hz had essentially replaced cps.

### Neurobiology and Biophysics

**Julius Bernstein (1839–1917).** Bernstein earned his medical degree under Emil du Bois-Reymond's supervision at the University of Berlin in 1862 (Seyfarth 2006). Bernstein had succeeded Wilhelm Wundt (see below) as Helmholtz's assistant at the University of Heidelberg in 1864 and succeeded Helmholtz as Interim Head of Physiology when Helmholtz left the Chair in Physiology at Heidelberg in 1871 to become the Chair in Physics at the University of Berlin. This writer has seen relatively little about Helmholtz's and Bernstein's personal relationship, but from what is available, it is clear that Bernstein was appreciative of Helmholtz.

It was during his time as Helmholtz's assistant that Bernstein accomplished that for which he is best remembered, namely, being the first to record the action potential of neurons (1866). He was able to do so using a special instrument (the *differential rheotome*) that he designed and constructed. Much later (1902) Bernstein published his membrane theory (see Seyfarth 2006, pp. 5–7), which enabled an understanding of the electrochemical basis for the action potential. In 1912, Bernstein published a treatise titled *Elektrobiologie*, which Seyfarth (2006, p. 7) summarized as follows:

His treatise amounts to the first quantitative theory of nerve- and muscle action based on solid experiments, exact measurements, and biophysical models that finally led to a paradigm shift in the understanding and further investigation of bioelectrical processes.

Bernstein was the first Jewish Rector (President) of a German university (the University of Halle).

Although antisemitism was widespread, Seyfarth (2006) found no evidence to indicate any discrimination against Bernstein. Such was not the case for Bernstein's sons. In 1933 when the Nazis came into power, Bernstein's two sons who held university faculty positions, respectively, at the University of Halle and at the University of Göttingen, were dismissed from their positions, and they and their families were forced into exile.

## Psychology

**Wilhelm Wundt 1832–1920.** Wundt is well remembered as the founder of Experimental Psychology at the University of Leipzig in 1879, that being the year he was assigned half a building for his research laboratory. Educated as a physiologist, it was as Professor of Philosophy that Wundt went to Leipzig. As “Wilhelm Wundt” is the subject of another entry in this Encyclopedia, information about Wundt here will be limited mostly to his association with Hermann von Helmholtz.

While earning his doctorate in medicine at the University of Heidelberg in 1856, Wundt also spent a semester studying with Johannes Müller in Berlin. After receiving his doctorate, Wundt remained at Heidelberg as a Dozent (lecturer). In 1858 Helmholtz arrived at Heidelberg as the Chair in Physiology. Wundt became Helmholtz's assistant. Regarding Helmholtz's and Wundt's relationship, Boring (1950, p. 319) wrote:

Altogether there seems to have been respect and mutual admiration between Helmholtz, 11 years senior, and Wundt, the junior, but no great personal intimacy.

Helmholtz and Wundt overlapped at Heidelberg for 14 years, but when it involved their research, each preferred to work independently. Nevertheless, Cahan (2018, p. 253) wrote:

They had a good working relationship, though, and Wundt greatly admired Helmholtz. [Paragraph Break] Helmholtz for his part, had a quite positive view of Wundt both as a teacher and as a researcher . . . . [Paragraph Break] Helmholtz also tried to help Wundt get Heidelberg to name him Extraordinary Professor of anthropology and medical psychology in the Medical Faculty . . . . Wundt received the Extraordinary Professorship the following year.

Wundt hoped to succeed Helmholtz in Heidelberg's Chair in Physiology, but as noted above, that appointment went to Julius Bernstein. Wundt stayed on at Heidelberg until he accepted a position in Philosophy at the University of Zurich in 1874. By then, part 1 (1873) and part 2 (1874) of Wundt's *Grundzüge der physiologischen Psychologie* (*Textbook of Physiological Psychology*) were published, and Wundt was leading the effort to have Psychology recognized as an independent discipline.

Regarding Psychology as a discipline, Helmholtz's research over his career has been described as physics, physiology, and psychology, but he believed firmly that the scientific aspects of psychology belonged in physiology, and the rest of psychology belonged in philosophy. Interestingly, in 1868, Helmholtz had written to du Bois-Reymond that “Philosophy is, incidentally, a dreadful wasp's nest, which one should never touch” (Cahan 2018, p. 533).

## Closing Remarks

### Helmholtz's Wives

It would be remiss to fail to mention Helmholtz's wives, both of whom Helmholtz clearly loved and respected. He married Olga von Velton in 1849 and with her had two children. However, after several years of failing health, she died in December 1859. About a year later, Helmholtz met Anna von Mohl. Despite their age difference (Anna, 26; Helmholtz, 39), they quickly realized they would be a good match. They were married in May 1861, approximately 18 months after Olga's death. Some saw it as an insult to Olga's memory, but most friends and family saw it as a good marriage, in part, because Anna was happy to assume the care of Helmholtz's children. Helmholtz and Anna were also a close match intellectually, and he named her to be his Literary Executor following his death. That duty included finalizing some of his unpublished manuscripts.

### Helmholtz's Ill Fated Voyage to the United States

In 1892, the Reich government asked Helmholtz to represent Germany at the International Electrical Congress in August in Chicago, USA. Being in less than optimal health, Helmholtz resisted initially but eventually agreed. Also being much concerned about Helmholtz, Anna requested and received funds from Germany's Chancellor to accompany him. The trip lasted from early August to early October. They visited many of the famous tourist sites (e.g., the Rockies and Niagara Falls) and were hosted and honored at several major universities, especially Columbia University where one of Helmholtz's students was an influential ophthalmologist. On the voyage home, while Anna was resting in their cabin, Helmholtz fell down a long set of stairs. He retained consciousness but was conveyed to the more comfortable captain's cabin where, according to Anna, he was ably attended by the ship's doctor. Helmholtz resumed his duties in November as Rector at the Imperial Physico-Technical Institute in Charlottenburg, but he never fully recovered. He died on September 8, 1894. Anna died in 1899 at age 66.

### Honors and Awards

It is fitting to end this brief biography of Helmholtz by listing a few of his major awards and honors.

- 1873. He received The Order of Merit for the Arts and Sciences. The award was established by Frederick Wilhelm IV (King of Prussia from 1840 to 1861) in 1842 to honor extraordinarily distinguished persons, and it was intended to be Germany's highest civilian award.
- 1883. Helmholtz attained nobility (viz., the title "von") at the instigation of the Crown Prince and Princess. Hereafter, he would be Hermann von Helmholtz. Such a title placed Helmholtz above most of his fellow scientists which caused him some concern, but he realized he could not deny the benefits of nobility to his family and descendants.
- 1889, June 6. Helmholtz's statue in front of the main building at University of Humboldt was dedicated (see below).

- In Charlottenburg, Berlin, the street *Helmholtzstraße* is named after von Helmholtz.

Statue of Hermann von Helmholtz at the University of Humboldt

## Hermaphrodite

Kevin A. Rosenfield  
 Pennsylvania State University, University Park,  
 PA, USA

## Synonyms

Alternative mating tactics; Dual sexuality; Sex changer

## Introduction

A hermaphrodite is an organism that possesses the reproductive organs of both sexes and can reproduce as either male (by producing sperm or pollen) or female (by producing ova). The term “hermaphrodite” has sometimes been used to refer to humans whose biological sex is ambiguous. This usage has fallen out of favor and in any case was technically incorrect. The essential characteristic of hermaphrodites is the ability to *reproduce* as both male and female. No such case has been identified in any human (Puts 2009).

## Types of Hermaphroditism

Hermaphrodites are divided into two categories: *simultaneous* and *sequential*. Simultaneous hermaphrodites are both male and female from the time of sexual maturity, whereas sequential hermaphrodites switch sexes one or more times during the lifespan. Sequential hermaphroditism is further divided into *protandry*, in which individuals mature as males and later change into females, and *protogyny*, in which females become males. In species with *bi-directional sex change*, individuals may begin as either male or female and subsequently switch to the opposite sex. *Serial sex changers* can change sexes more than once (Avisé 2011). In contrast to hermaphrodites, *gonochorous* organisms, such as most mammals, possess the reproductive organs of only one sex throughout the lifetime.

The overwhelming majority of animal mating systems are either *dioecious* (in which all individuals are gonochorous) or hermaphroditic (all individuals are hermaphrodites). *Androdioecy*, by contrast, is a rare mating system in which males and simultaneous hermaphrodites of the same species coexist. Cases of gynodioecy, in which breeding groups are made up of females and simultaneous hermaphrodites, are even less common but are found in some angiosperm plant species (Bawa 1980). Among simultaneous hermaphrodites, *self-fertilization* is possible and is common in some (mostly plant) species, whereas it is totally absent in others, such as several simultaneously hermaphroditic fish.

## Examples of Hermaphroditism

Examples of simultaneous hermaphrodites include most (80%) angiosperm flowering plants (Willmer 2011), approximately 25 fish species (Avisé 2011), and all oligochaetes (a class of animals that includes earthworms; Purves 2004). Approximately 250 (1%) of the world's teleost (bony) fish species are hermaphroditic. The vast majority of these are sequential and protogynous hermaphrodites, although there are also cases of protandry, bi-directional sex change, and simultaneous hermaphroditism. Among hermaphroditic invertebrates, most species are simultaneous hermaphrodites, but at least 15 classes, including the limpets (class Gastropoda), are primarily

protandrous. Several species of corral-dwelling gobies (fish in family Gobiidae) express serial, bi-directional hermaphroditism, starting as either males or females and switching sexes one or more times throughout life (Avisé 2011).

### Evolution of Hermaphroditism

Several potential explanations for the evolution (via natural selection) of hermaphroditism have been advanced. Because sequential and simultaneous hermaphroditism each comes with its own set of reproductive and energetic costs and benefits, no single adaptive explanation will suffice, but all such explanations have one thing in common: Sex change is adaptive if it increases individual reproductive success.

The *size-advantage hypothesis* posits that sequential hermaphrodites begin as members of the sex with higher reproductive potential at small sizes and switch to the opposite sex when they have attained a body size at which the that sex's potential reproductive success is higher (Munday et al. 2006). The *risk-of-movement hypothesis* has been proposed to account for the evolution of serial bi-directional sex change in several species of fish. It posits that in sparsely distributed species with high predation risk, individuals change sex in order to avoid risky mate searching when mates of the same, but not the opposite, sex are available in the immediate home range (Avisé 2011). Finally, a prominent explanation for the evolution of simultaneous hermaphroditism is the *low-density model*. This model suggests that when organisms live at low population densities, encounters with members of the opposite sex may be extremely infrequent but can be doubled if each individual possesses the reproductive organs of both sexes (Ghiselin 1969).

## Heterogametic

Meghna Singh Dhaka  
IMS Engineering College, Ghaziabad,  
Uttar Pradesh, India

### Synonyms

[Heterozygous chromosomes](#)

### Definition

Heterogametic means nonuniform distribution of sex-chromosomes in an organism.

## Heterogametic

Heterogametic describes presence of different types of sex chromosomes in an organism. Heterozygosity is mostly associated with sex

chromosomes than autosomes and plays a key role in sex-determination among organisms. For example, in case of human beings, XY chromosomes define a male sex while XX chromosome represents a female sex. Sex chromosomes are present as single copy in an organism and complement the gene product quantity through dosage compensation or the meiotic silencing (Forsdyke 2000; Johnson and Lachance 2012). Sex chromosomes show strong impact of evolutionary processes (mutation, selection, genetic drift, and meiotic drive) and play an important role in natural phenomena like hybrid incompatibility and speciation. Besides animals and birds, heterogametic chromosomes are occasionally observed in plants also (Johnson and Lachance 2012).

Sex chromosome systems vary considerably. In some organisms, as in mammals and many insects, the males are heterogametic (have two different sex chromosomes) and females are homogametic (have two of the same sex chromosome) (Ellegren 2011). In others, such as birds and butterflies, females are heterogametic and males are homogametic.

Because of varied chromosomes, the modes for sex determination are also different in all organisms. The method used for determination of sex helps to understand the evolution of heterogametic nature in different sexes. Like in the Protenor mode of sex determination as XO and the Lygaeus mode of sex determination as XY. In some species like chickens and in moths, the heterogametic sex chromosomes exist in the female. The distribution of chromosomes does affect the fertility of these organisms; like in case of birds and Lepidopterans, females (also known to be heterogametic) are more often inviable or sterile, while in the mammals the heterogametic males are more often affected (Vicoso and Charlesworth 2006; Turner 2007).

It is suggested that presence of heterogametic sex chromosomes could be due to inviability or sexual transformation. Haldane's rule also supports heterogametic nature of chromosomes.

As said above female heterogamety is also prevalent in many organisms including birds, reptiles, amphibians, fishes, crustaceans, and moths and butterflies. Among these also, birds, moths,

and butterflies are known to consistently follow heterogamety through many generations while in case of moths and butterflies only a small minority works this way.

Other than male and female, heterogametic nature of sex chromosomes is also dependent on environment factors – environmental sex determination. For example, in case of birds, Z and W chromosomes are largely homologous in all species. In Lepidoptera, data from a limited number of species suggest that the Z chromosome has retained conserved synteny across the whole group. Moreover, female heterogamety is also found in caddis flies (Trichoptera), the sister group to moths and butterflies, suggesting that their sex chromosomes had already started to evolve in a common ancestor of Lepidoptera and Trichoptera more than 190 million years ago (Malcom and Wyckoff 2003; Ellegren 2011; Forsdyke 2000). Various factors involved in causing heterogametic nature of sex chromosomes are:

### Mutation

The mutation rate is usually much higher in males than in females because developing male gametes usually undergo many more rounds of replication than do female gametes.

### Random Genetic Drift

Sex chromosomes and autosomes also experience differential effects from random genetic drift.

### Selection

Various forms of selection such as sexual antagonism influence the differential evolution of sex chromosomes and autosomes.

### Female Heterogametic Systems

Birds and snakes are the two major vertebrate groups with ZZ/ZW sex chromosomes (i.e., females are heterogametic).

## Synonyms

[Heterozygote advantage](#); [overdominance](#)

## Definition

Heterozygote superiority (heterozygous advantage) is the case or state in which the heterozygous genotype has a higher relative fitness due to the overdominance in contrast to homozygous dominant or homozygous recessive genotype.

## Introduction

The term heterozygote superiority was first proposed by Fisher in 1923. The phrase heterozygote advantage is often used as a synonym for heterozygote superiority. Heterozygote superiority (heterozygous advantage) describes the case in which the heterozygous genotype has a higher relative fitness than either the homozygous dominant or homozygous recessive genotype.

In population studies, mean fitness of heterozygotes is higher than the mean fitness of all homozygotes, but in laboratory studies and evolutionary models, heterozygotes are superior to both parental homozygotes. Heterozygote superiority is fascinating because it is mysterious that why seemingly harmful mutations like those causing fatal diseases still exist in populations today which should be eliminated by natural selection. It might be possible that some form of balancing and diversifying selection is operating consistently over long periods of evolutionary time. Genetic variations in natural populations as well as heterosis or hybrid vigor are the ultimate results of heterozygote superiority because heterozygote superiority, or heterozygote advantage, play very important role in maintenance of variations in population by selection.t

Gillespie Model

Before Gillespie model, it was believed that reason behind the heterozygote superiority was complementation (or dominance) or the masking of deleterious recessive alleles by wild-type alleles, but Gillespie model in the year 1974 revealed that the main cause behind heterozygote superiority is overdominance. Population geneticist John H. Gillespie established the following model:

|                   |      |      |      |
|-------------------|------|------|------|
| Genotype:         | A1A1 | A1A2 | A2A2 |
| Relative fitness: | 1    | 1-hs | 1-s  |

where h is the heterozygote effect and s is the recessive allele effect. Thus, given a value for s (i.e.,  $0 < s < 1$ ), h can yield the following information:

- h = 0: A1 dominant, A2 recessive
- h = 1: A2 dominant, A1 recessive
- $0 < h < 1$ : incomplete dominance
- h < 0: overdominance
- h > 1: underdominance

The case  $h < 0$  in the Gillespie model is the possible explanation for the case of heterozygote superiority.

Elemental Force Behind the Heterozygote Superiority

Heterozygote superiority necessarily involves some combination of the major evolutionary processes: mutation, genetic drift, and natural selection. We will consider each of these in turn.

Mutation

One possible explanation for a high frequency of deleterious alleles at a particular locus is that the gene in question has a particularly high mutation rate (Valles 2010). However, some mutations that are associated with disease have been found only rarely, and the known pattern of allelic variation across the gene was not suggestive of a particularly high mutation rate. Additionally, if the mutation rate of the gene was extraordinarily high, it would be difficult to explain why the frequency of disease is high only in specific area.

Genetic Drift

Wright and Morton (1968) argued that while it was very unlikely for a recessive lethal allele to drift to as high frequency, there are thousands of potential lethal mutations across the genome. Most researchers have a rejected the possibility of genetic drift as responsible for the observed incidence of heterozygote superiority because in most of the cases of disease, population has been too large or too long for drift to be a plausible explanation.

Natural Selection

Natural selection has historically acted very strongly against mutations in homozygotes. Role of selection in developing and maintaining the high frequency of mutated alleles must therefore be through some advantage to heterozygotes with one mutated allele and one fully-functional allele. Thus, this is clear that the natural selection plays very important role in heterozygote superiority.

All the factors which have been discussed above might contribute synergistically for the heterozygote superiority.

## Evidences in Favor of Heterozygote Superiority

Numerous cases of heterozygote superiority have been demonstrated in several organisms, including humans. The first experimental confirmation of heterozygote superiority was with *Drosophila melanogaster*, a fruit fly that has been a model organism for genetic research. However, most of the examples of heterozygote superiority are associated with disease resistance and are maintained only in the presence of disease or other gene–environment interaction.

### Sickle-Cell Anemia

Sickle-cell anemia (SCA) is a genetic disorder caused by the presence of two incompletely recessive alleles. When a sufferer's red blood cells are exposed to low-oxygen conditions, the cells lose their healthy round shape and become sickle-shaped. This deformation of the cells can cause them to become lodged in capillaries, depriving other parts of the body of sufficient oxygen. The genetic disorder is incompletely recessive; a person with only one SCA allele and one unaffected allele will have a “mixed” phenotype: The sufferer will not experience the ill effects of the disease, yet will still possess a sickle cell trait, whereby some of the red blood cells undergo benign effects of SCA, but nothing severe enough to be harmful. However, convincing evidence indicates, in areas with persistent malaria outbreaks, individuals with the heterozygous state have a distinct advantage (and this is why individuals with heterozygous alleles are far more common in these areas). There were selective advantages because if there were no selective advantage to the recessive allele, we would expect it to slowly be removed from the gene pool, and the frequency of individuals with sickle cell disease should approximate the mutation rate of the normal A allele to the S allele, which is extremely rare. Heterozygote AS is resistant to the malarial parasite *Plasmodium falciparum*, so copies of the S allele are lost from the gene pool when they occur in individuals affected with sickle cell disease since they do not reproduce, but more copies are created in the offspring of AS individuals. The heterozygote

advantage of the sickle-cell gene is context-dependent and depends on the frequency of the protozoan parasite in the population, outside malaria-infested areas. In this instance, the state of the organism's environment will provide selection, with a net effect either favoring or working in opposition to the gene, until an environmentally determined equilibrium is reached. Thus, heterozygote superiority in case of sickle cell anemia is a perfect example of GxE.

### Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive hereditary monogenic disease of the lungs, sweat glands, and digestive system. The disorder is caused by the malfunction of the CFTR protein, which controls transport of chloride ions, which is vital to maintaining equilibrium of water in the body. The malfunctioning protein causes formation of viscous mucus in the lungs and intestinal tract. Earlier, children born with CF would have a life expectancy of only a few years.

The presence of a single CF mutation may influence survival of people affected by diseases involving loss of body fluid, typically due to diarrhea because the heterozygote had less secretory diarrhea than normal, homozygote. Thus, it appeared that resistance to cholera explained the selective advantage or heterozygote superiority to being a carrier for CF.

Another theory for the prevalence of the CF mutation is that it provides resistance to tuberculosis. Thus, CF heterozygotes affected the survival of typhoid fever, secretory diarrhea (including cholera), and tuberculosis (Valles, 2010).

### Triose Phosphate Isomerase

Triose phosphate isomerase (TPI) is a central enzyme of glycolysis, the main pathway for cells to obtain energy by metabolizing sugars. In humans, certain mutations within this enzyme, which affect the dimerization of this protein, are causal for a rare disease, triose phosphate isomerase deficiency. Other mutations, which inactivate the enzyme (= null alleles), are lethal when inherited homozygously (two defective copies of the TPI gene), but have no obvious effect in

heterozygotes (one defective and one normal copy). However, the frequency of heterozygous null alleles is much higher than expected, indicating a heterozygous advantage for TPI null alleles.

### Resistance to Hepatitis C Virus Infection

There is evidence that genetic heterozygosity in humans provides increased resistance to certain viral infections. A significantly lower proportion of HLA-DRB1 heterozygosity exists among HCV-infected cases than uninfected cases. These statements constitute evidence that heterozygosity provides an advantage among carriers of different supertype HLA-DRB1 alleles against HCV infection progression to end-stage liver disease in a large-scale, long-term study population (Hraber et al. 2007).

### MHC Heterozygosity and Human Scent Preferences

Females prefer the scent of males who are heterozygous at all three MHC loci. However, it has been argued that heterozygosity at MHC loci results in more alleles to fight against a wider variety of diseases; possibly increasing survival rates against a wider range of infectious diseases because heterozygosity enhanced their health and survival rates against multiple-strain infections. Heterozygote individuals can have higher fitness (heterozygote superiority) due to higher resistance to multiple parasites (Hedrick, 2012). MHC heterozygotes are expected to be superior to both homozygotes because they can present a wider variety of peptide antigens to T lymphocytes, the triggering event of the adaptive immune response. Heterozygote superiority is expected to emerge after serial or simultaneous coinfections when resistance is dominant and the susceptibility profiles of two pathogens are opposite or reciprocal (Potts and Slev 1995). We will refer to this as the dual infection heterozygote superiority (DIHS) hypothesis because when animals are infected with two pathogens that show opposite susceptibility profiles, heterozygotes are found to be superior, whereas when animals are infected with two pathogens that show similar susceptibility profiles, heterozygotes are predicted to be intermediate.

### BAFF and Autoimmune Disease

B-cell activating factor (BAFF) is a cytokine encoded by the TNFSF13B gene. A variant of the gene containing a deletion (GCTGT→A) renders a shorter mRNA transcript that escapes degradation by microRNA, thus increasing expression of BAFF, which consequently upregulates the humoral immune response. This variant is associated with systemic lupus erythematosus and multiple sclerosis, but heterozygote individuals have decreased susceptibility to malaria infection (Steri et al. 2017).

### Livestock and Pets

There are a number of mutants in livestock and pets that have heterozygote superiority because of artificial selection for these mutants in heterozygotes and strong detrimental effects from natural selection in homozygotes. In livestock, these mutants include ones that influence milk yield in dairy cattle, fecundity in sheep, litter size in pigs, muscling in beef cattle, color in horses, lean meat content in pigs, and comb morphology in chickens. In pets, these mutants include ones that influence tail length in cats and hairlessness, muscling, color, or ridgeback hair in dogs.

### Other Examples

The allelic trichromacy of long-to-middle wave sensitive (L/M) opsins in New World monkeys is a good example of heterozygote superiority (Hiwatashi et al. 2010). As trichromatic females in a population of wild white-faced capuchins (*Cebus capucinus*) are more accurate in selecting ripe, reddish fruits than are males or dichromatic females. Females heterozygous for the L/M opsin are capable of trichromatic vision, whereas the remaining homozygous females and all males are dichromatic.

The fertility polymorphisms documented in BMP15 and GDF9 also represent one of the best examples of heterozygote superiority yet described, with the genetic basis, fitness differentials, and the mechanism of selection well understood (Hanrahan et al. 2004).

21-hydroxylase deficiency is an autosomal recessive disorder due to mutations in the 21-hydroxylase gene (CYP21) located on the

short arm of chromosome 6 where it lies in close proximity to a nonfunctional pseudogene (CYP21P). In affected homozygotes, decreased adrenal 21-hydroxylase activity interferes with cortisol and aldosterone biosynthesis, adrenal androgen biosynthetic pathway intact, but there is a survival advantage to 21-hydroxylase heterozygotes as adrenal gland of heterozygotic carriers would be upregulated or primed to secrete cortisol, because the clinically imperceptible decrease in cortisol secretion had led to increased ACTH secretion.

## Conclusion

Even after many decades, it is hard to portray about heterozygote superiority as it is an important and very diplomatic phenomenon in biology because as a coin has positive and negative both, heterozygous superiority is also the case of the negative positive genetics as heterozygote superiority is the case where the heterozygote carries both advantages and disadvantages, while both homozygotes carry a disadvantage. For example, heterozygotes of flowering plants will provide high yield and may show high vigor with pest resistance to disease tolerant, but on negative sides, if heterozygosity increases in case of plants, it will increase infection rate, host invasion, lethality, and drug resistance, even these heterozygotes show high survival rate and eco-climatically adapted.

## Definition

Hibernation is a physiological mechanism used by heterothermic animals to conserve energy. It is a process classically categorized by lowering one's metabolic rate or heart rate, reducing body temperature, and regulating oxygen consumption. The intensity of these processes varies between taxa and can fluctuate from daily to multiday torpor (hibernation).

## Introduction

Endotherms have high energy requirements and maintain their core body temperature ( $T_b$ ) by means of heat production. Maintaining  $T_b$  in itself is energetically costly but is required for proper cell function, reproduction, and behavioral efficiency (Geiser 2013; Martin 2001). Endothermic animals regularly exhibit what is called hypometabolism during periods of inactivity, where an individual lowers their normal metabolic rate by an average of 20% and most often in conjunction with lowering  $T_b$  by  $\sim 2^\circ\text{C}$  (Heldmaier et al. 2004). Heterothermic animals are endotherms with the capacity to adjust their body temperature to their environment, well below this threshold.

Endothermy is understood to have evolved independently twice, once in birds and once in mammals. Birds and mammals originate from distinct reptilian lineages, with bird endothermy having evolved much later than in mammals. Heterothermy is a primitive trait of pre-mammals, with an original purpose to cope with low metabolism. Now, scientists suggest hibernators use heterothermy as a method of conserving energy. Thus, an increased metabolic rate in extant mammals would be an adaptation for conserving energy (Rial et al. 2010).

Due to a larger surface area (relative to body size), smaller animals experience more heat loss and are more affected by seasonal and climatic changes in their environment. These animals are more likely to be heterothermic, in order to cope with such energetic challenges. In environments with extreme climates or seasonal stressors (i.e.,

when resources are scarce), heterothermic animals can conserve energy by using a prolonged period of hypometabolism, such as torpor (Geiser 2004; Ruf and Geiser 2015). Torpor is a state of lethargy where an organism notably lowers its metabolic rate, core  $T_b$ , heart rate, and oxygen. Animals that use this mechanism vary from levels of daily torpor (often referred to as daily heterothermy) to multiday torpor (hibernation). In regard to endothermic animals, torpor and hibernation are the most effective methods for conserving energy in demanding environments (Geiser 2013).

Daily heterotherms will enter a torpid state for a few hours during a part of the day and at a lesser degree – most frequently defined as animals lowering their body temperatures below  $\sim 30^\circ\text{C}$ , but not lower than  $15^\circ\text{C}$ . Hibernators, on the other hand, will remain torpid for multiple days or an entire season and are characteristic of lowering their  $T_b$  well below  $15^\circ\text{C}$ , closer to  $5^\circ\text{C}$  (deep or “true” hibernation).

## The Process of Hibernation

During the process of hibernation, an individual reduces their metabolic rate to a fraction of their basal metabolic rate, while lowering their body temperature well below normothermia. Normothermia is the condition where an individual is within their normal body temperature range, which for birds and mammal is around  $37^\circ\text{C}$  (Heldmaier et al. 2004). Hibernators rely heavily on metabolic inhibitions in addition to  $T_b$  adjustments to reduce their metabolic rate, whereas daily heterotherms can rely more on  $T_b$  to lower their metabolic rate (Geiser 2004).

Hibernators often adjust into a specific body posture when they become torpid, similar to the posture they enter for natural sleep (Lyman et al. 1982). In this posture, the animal will position the back to an insulating material or structure, such as a nest, tree hole, or burrow. Tucking the head under the chest keeps the heart warmer than the body when an animal lowers its  $T_b$ . This posture helps to maintain optimal thermal comfort while minimizing any sudden changes in ambient

temperatures during hibernation that might disrupt the process. To further decrease exposure of body surface, some species hibernate in groups or huddled together – this is often referred to as “social thermoregulation” (Bright and Morris 1991; Lyman et al. 1982; Masing and Lutsar 2007; Mueller 1999).

Throughout the process of hibernation, an animal will go through periodic arousals where they self-generate heat, a process called euthermy, to increase their body temperature gradually toward normothermy. Sporadic arousal within torpor (inter-bout arousal) is the greatest energy expenditure of the entire hibernation process (Thomas et al. 1990).

As arousal is an energetically costly process, some animals save energy by the use of behavioral thermoregulation, such as sun-basking, or the use of postural and locomotion adjustments that help to conserve and generate heat (Whittow 2013). Basking behavior is frequently used by species with a low metabolic rate, such as marsupials. In addition to being an energy-saving method, basking also saves time, decreasing the amount of time spent in arousal (Geiser 2004).

After complete arousal at the end of a hibernation bout, an animal will begin semi-passive behavior, exploring and assessing its surrounding environment. This behavior is known as risk assessment behavior (RAB), where the animal assesses the safety of their surroundings (e.g., predators, competitors, resource availability) with vigilance and scanning. After RAB, an animal will begin what is called goal-directed behavior. Goal-directed behavior can range from foraging to searching for mates to locating a safe place of rest (Cooper et al. 2003).

## Hibernators

As technology improves, physiological research in the field has expanded our abilities to understand better the processes of torpor and hibernation in wild animals. Species that were previously unknown to be heterothermic were studied extensively in captivity. Expanding research in the field has brought us to learn that some species use

torpor regularly in the wild or only in response to extreme environmental changes (Geiser 2013). Animals that are capable of daily torpor include birds, bats, and various species of mammal. Less species are known to use the extreme process of hibernation, including only one known species of bird, insectivorous bats, and a handful of mammals, discussed below.

### Birds

Birds display a greater level of hypometabolism in their inactivity phase, where they are capable of regularly decreasing their metabolic rate by 30% and lower their  $T_b$  by 4 °C (Heldmaier et al. 2004). The common poorwill *Phalaenoptilus nuttallii* is the only bird species known to hibernate (Woods and Brigham 2004). Other birds (i.e., hummingbirds and the tawny frogmouth *Podargus strigoides*) are known to be daily heterotherms but do not enter a torpid state long or deep enough to be considered hibernators (Geiser 2013).

### Chiroptera

Only the insectivorous (insect eating) bats are known to use hibernation, whereas the frugivorous (fruit eating) bats have only been found to use daily heterothermy. Insectivorous bats fall within the genus *Chiroptera* with known hibernating species being *Barbastella barbastellus*, *Eptesicus fuscus*, *Myotis lucifugus*, *M. myotis*, *Nyctalus noctula*, *Nyctophilus geoffroyi*, *N. gouldi*, *Pipistrellus pipistrellus*, and *Tadarida brasiliensis*.

### Mammalia

#### Monotremata

The short-beaked echidna, *Tachyglossus aculeatus*, is the only monotreme species known to hibernate (Lyman et al. 1982). This species maintains a normothermic average of 32.2 °C, with the lowest recorded  $T_b$  of 4 °C, and will most often arouse from hibernation for mating (Geiser 2004).

#### Marsupialia

Marsupials are unique among the hibernators. Marsupials began as poikilotherms, which later evolved into homeothermy followed by

heterothermy. This means the physiological ability to withstand cold temperatures is plesiomorphic (Rial et al. 2010). There are currently four known hibernating marsupials, belonging to the genera *Acrobates*, *Burramys*, *Cercartetus*, and *Eudromicia*. *Acrobates pygmaeus*, the feathertail glider, is a species that uses both torpor and hibernation, depending on the environmental stressors, namely, ambient temperatures. They are true hibernators based on the degree to which they lower their body temperature and metabolic rate; however, they do not perform pre-hibernation fattening as many species do (Geiser 1994). The marsupial mountain pygmy possum, *Burramys parvus*, is a seasonal hibernator, ranging in high altitude mountains. The eastern pygmy possum *Cercartetus nanus* can enter hibernation for up to five weeks during any time of the year, with a body temperature as low as 1–6 °C (Geiser 1994). The little pygmy possum *Eudromicia lepidia* has been observed to enter multiday torpor for a total of 12 days (Bartholomew and Hudson 1962).

#### Placentalia

The state of hibernation in placental mammals is entered through a process of sleep called slow-wave sleep (SWS). Of the mammalian subgroups, placentals have the most hibernators. Rodents have been studied, arguably, most thoroughly of all the placental hibernators. This is largely due to the convenience of studying them in captivity, their small body size, and the variations discovered between species of Rodentia. There are many species of rodent that use hibernation and so have been a large focus for understanding the mechanisms and interpretation of thermoregulation by animals (Whittow 2013).

The Arctic ground squirrel *Spermophilus parryii* is especially unique, as it can lower its body temperature below freezing, to –2.9 °C (Barnes 1989). The golden-mantled ground squirrel (*Callospermophilus lateralis*) has been recorded to enter hibernation for as long as 16 consecutive days (Pengelley and Fisher 1961). Due to the large quantity of hibernating rodents, here we note a few of the most notable: *Eliomys quercinus*, *Glis glis*, *Marmota flaviventris*, *M. marmota*,

*M. monax*, *Mesocricetus auratus*, *Spermophilus lateralis*, *S. tereticaudus*, *S. mexicanus*, *S. citellus*, *S. saturatus*, *S. mohavensis*, *S. richardsonii*, *S. parryii*, *Tamias amoenus*, *T. striatus*, *Zapus hudsonicus*, and *Z. princeps*.

Aside from rodents, placental hibernators range very diversely in body mass from the small insectivores, such as shrews, to as large carnivores, such as bears. A handful of elephant shrews are known to be short-term hibernators, including Cape rock elephant shrew *Elephantulus edwardii*, *E. rozeti*, and *E. myurus*. The common tenrec *Tenrec ecaudatus* is an insectivore endemic to the island of Madagascar. This species can hibernate for up to 9 months of the year (most commonly during the austral winter) and is unique among mammalian hibernators in their lack of displayed inter-bout arousal (Lovegrove et al. 2014). Hibernating hedgehogs including the European hedgehog *Erinaceus europaeus* can lower their body temperature to as low as 2 °C. There is one species of armadillo that is known to hibernate, the pichis *Zaedyus pichi*. This species uses both hibernations during the cold winter season and daily heterothermy during the non-hibernating season (McNab 1980).

Of the Primates, only two species are so far known to be hibernators, the Western fat-tailed dwarf lemur *Cheirogaleus medius* and the pygmy slow loris *Nycticebus pygmaeus*. Other species are known to use daily torpor, including *Microcebus murinus* and *Galago moholi* (Nowack et al. 2013).

Bears (black bear *Ursus americanus*, grizzly bear *Ursus arctos horribilis*) and badgers (e.g., Japanese badger *Meles anakuma*) are not true hibernators, but rather experience shallow hibernation. While bears display all of the characteristics of a true hibernator, such as seasonal hibernation and storing fat pre-hibernation, they only lower their body temperature by a few degrees.

## Sleep and Hibernation

The state of hibernation is entered and exited through slow-wave sleep (SWS), which is also

known as non-rapid eye movement or NREM (Rial et al. 2010). Because of this transition, hibernation and sleep were considered to be related physiological states, with hibernating individuals achieving both energy conservation and sleep benefits simultaneously (Walker and Berger 1980). Recently, however, neuroscientists have discovered that hibernation and sleep may be distinct physiological states, with hibernation preventing the entering of REM (rapid eye movement) or complete restorative sleep.

Most often, an arousing hibernator will locate a safe resting place to return to slow-wave sleep, where they display sleep rebounds. Sleep rebound has been observed to be more intense with a greater drop in  $T_b$  during hibernation, suggesting hibernating individuals are experiencing sleep deprivation (Rial et al. 2010). While sleep rebound is not displayed in all hibernating species, it is most prominently observed in mammals, unsurprisingly, as they require adequate sleep for physiological and cognitive functions. While inter-bout arousal throughout the hibernation process is still largely unknown, some researchers suggest this too may be correlated to sleep rebound, and animals are regularly exiting hibernation to experience brief sleep rebounds.

Furthermore, only birds and mammals are known as true sleepers, while reptiles and other animals only experience rest. This is largely due to their distinct physiological changes, as well as presence of different sleep stages. However, animals considered to only rest have displayed a rest rebound, similarly to sleep rebound in birds and mammals (Rial et al. 2010).

## Hidden Humans

### ► Turing Test

## Hippocampus

Eric J. Leonardis

Department of Cognitive Science, University of California, San Diego, La Jolla, CA, USA

### Definition

The hippocampus (from the Greek “seahorse”) is a brain structure located in the medial temporal

lobe that is primarily responsible for mapping spatial relations, temporal sequence information, and the formation of episodic memories.

### Introduction

The hippocampus (from the Greek “seahorse”) is a brain structure located in the medial temporal lobe that is primarily responsible for mapping spatial relations and the formation of episodic memories. The hippocampus is commonly described as being made up of the cornu ammonis (divided into sub regions CA1, CA2, CA3) and dentate gyrus. The “hippocampal formation” may also include the subiculum, parasubiculum, pre-subiculum, and entorhinal cortex (See Fig. 1). The hippocampus’ main computational functions are thought to involve pattern separation, pattern completion, and distributing new memories to cortex via memory consolidation (McNaughton and Morris 1987). Spatial theories of hippocampal function argue that its neurons form an allocentric spatial map that tracks an animal’s position and movement through space, allowing for the computation of online spatial relations like shortcuts. Theories of hippocampus suggest that it is central to relational or episodic memory that link together temporal, perceptual, spatial, and contextual information into unique events and common elements (Ergorul and Eichenbaum 2004).

### Historical Developments

In 1547, the hippocampus was first described by Julius Caesar Aranzi, a Venetian anatomist who compared the shape of the structure to both a silk worm and a sea horse. Vicq d’Azyr made a distinction between the hippocampus major and minor (now identified as the calcar avis). In 1742, De Garengeot chose the term cornu ammonis (CA) to describe the region, which invoked the ancient Greek God Ammon (related to the Egyptian God Amun), who is often represented as possessing the horns of a ram (Falougy and Benuska 2006).

**Hippocampus, Fig. 1** The hippocampal formation including the cornu ammonis subregion (CA1, CA2, CA3), dentate gyrus (DG), subiculum (Sub), presubiculum (PrS), parasubiculum (PaS), and lateral (LEA) and medial (MEA) entorhinal area (Permission granted by Lara Rangel and Jon Rueckemann)

In the early days of evolutionary theory, surrounding the publication of Darwin's *On the Origin of Species*, there was a public debacle known as the Great Hippocampus Question. In 1857, Richard Owen suggested that the hippocampus minor (now classified as the calcar avis) was unique to humans, and that it was not present in monkeys. In 1858, Thomas Henry Huxley (affectionately known as Darwin's Bulldog) grew irritated and systematically dissected multiple monkeys to collect evidence against Owen's case. Huxley and Owen's debate became public in 1860 at a debate on evolution at Oxford University, culminating in a heated series of lectures and publications between Owen and Huxley, eventually leading to Owen's more systematic refutation by William Henry Flower in 1862. The "Great Hippopotamus Test" was immortalized in Victorian culture in 1862 by Charles Kingsley who published a children's book *The Water-Babies, A Fairy Tale for a Land Baby* satirizing the incident. By 1866, Owen had retracted his previous statements about monkeys lacking this structure

and admitted his mistaken view in his book *On The Anatomy of Vertebrates* (Gross 1993).

In 1873, Golgi developed a new method of using silver staining techniques to uncover the structure of the axons, cell bodies, and dendrites of neurons. Ramon y Cajal (1911) perfected Golgi's method and used this method to study the connectivity of individual neurons in hippocampus. In 1934, Cajal's student Lorente de No provided the anatomical descriptions of the CA regions that are widely accepted today (Falougy and Benuska 2006). In 1937, Papez proposed that emotional experience was rooted in connectivity between the hypothalamus and medial temporal areas. Building on Papez's theory, (MacLean 1949) suggested that the hippocampus along with the amygdala, septum, and hypothalamus was part of the "visceral brain" or "limbic system" which was primarily recruited for the generation of emotional experiences.

In the 1950s, the Montreal Neurology Group lead by Wilder Penfield searched for the mechanistic origins of temporal lobe epilepsy (Penfield et al. 1952). A significant advance in identifying the functional role of hippocampus came from the famous case study of patient H. M. (after his death identified as Henry Molaison). H. M. suffered from major temporal lobe seizures and lapses of consciousness multiple times daily, and Dr. William Beecher Scoville decided to remove the hippocampus bilaterally with hopes of relieving the symptoms. After the removal of his hippocampus (along with surrounding tissue) bilaterally, H. M. was unable to form new episodic memories, having a condition known as anterograde amnesia. Brenda Milner gave H. M. a battery of psychological tests to empirically determine the memory deficits of bilateral hippocampal lesions in humans and demonstrated that other lesions to related medial temporal areas like the amygdala did not have the same types of memory deficits (Scoville and Milner 1957).

While the hippocampus was established as playing an important role in emotion and memory formation, by the early 1970s, the discovery of spatially selective cells, known as "place cells" in the rodent hippocampus, led the field to focus primarily on its role in navigation (O'Keefe and

Dostrovsky 1971). This fascinating one to one mapping between cellular function and the external environment was conducive to extensive empirical investigation. Consideration of the hippocampus' role in temporal processing and context have served a unifying role between the navigation literature on hippocampal function in rodents to that of the formation of episodic memory.

### **Hippocampal Neuroanatomy: Gross Anatomy and Microcircuitry**

The hippocampus is a three layered brain structure described as being made up of the cornu ammonis (CA1, CA2, CA3) and dentate gyrus. The first layer is known as the stratum oriens, which has a mixture of afferent and efferent projections and interneurons. The second layer is called the stratum pyramidale. The third layer is known as the stratum moleculare, which in CA3 is further divided into the stratum lucidum, stratum radiatum, and the stratum lacunosum-moleculare. The CA regions and DG regions are present throughout the dorsal, intermediary, and ventral portions of hippocampus (Amaral and Witter 1989; van Strien et al. 2009).

The trisynaptic loop is the canonical circuit described by Ramon y Cajal and De No (1911) which reciprocally connects cortex and hippocampus completing what is known as the cortico-hippocampal loop (Andersen 1975). The first synapse of the trisynaptic circuit is made by pyramidal cells in lateral entorhinal cortex (IEC) layer II, whose axons perforate through the subiculum, synapsing onto the granule cells of the dentate gyrus. These bundles are known as the perforant pathway (Amaral and Witter 1989). The mossy fiber pathway is a set of axons which project from the granule cells of the dentate gyrus to the pyramidal cells of CA3 forming the second synapse of the trisynaptic circuit (Van Strien et al. 2009). Pyramidal cells from CA3 project axons, known as the Schaffer collaterals, up to CA1 where they converge on CA1 pyramidal cells' apical dendrites. This is where CA1 pyramidal cells project back to deep layers of the entorhinal

cortex, completing the hippocampal-cortical loop (Amaral and Witter 1989; Van Strien et al. 2009). The trisynaptic pathway is a robust pathway present in all mammals and is a general organizing principle for understanding hippocampal processing.

The trisynaptic circuit describes a robust set of connections, but there is additional connectivity which was not included in the canonical circuit. There are also projections from medial and lateral entorhinal cortex onto CA1, with lateral entorhinal inputs converging onto the dendrites of CA1 cells located closer to subiculum, and the medial entorhinal inputs converging onto the cells closer to CA3 (Steward 1976). Interestingly, area CA2 has been historically left out of the circuit altogether. CA2 pyramidal cells project onto CA1 dendrites, and have been shown to drive CA1 activity when stimulated. It has been found that the granule cells in the dentate gyrus also converge onto CA1 cells and also project axons to area CA2. CA2 pyramidal cells receive input from the supramammillary nucleus and vasopressinergic cells from the paraventricular nucleus of the hypothalamus (Dudek et al. 2016).

In regards to extrahippocampal connections, the parahippocampal region is a six layered cortical region highly integrated with the hippocampal formation and includes the presubiculum, parasubiculum, entorhinal cortex (medial and lateral), perirhinal cortex, and postrhinal cortex. The hippocampus has major output pathways to the subiculum, retrosplenial cortex, parietal cortex, and lateral septal nucleus. The hippocampus also has connectivity with the medial prefrontal cortex, which supports temporal sequence processing (Van Strein et al. 2009).

### **Computational Roles of Hippocampal Subregions**

The dentate gyrus has many more neurons than the inputs it receives from entorhinal cortex, which then project back down to a smaller number of neurons in CA3. This structural property suggests that the dentate gyrus may have an ability to perform a computational process known as

pattern separation. This separation process involves taking highly similar inputs, projecting those input patterns onto a larger population of cells, allowing for the generation of more differentiated output pathways than the initial inputs (Deng et al. 2010). The perforant pathway between the EC and the DG was the site of the discovery of long-term potentiation (LTP) (Bliss and Lomo 1973). Long-term potentiation is believed to be a primary mechanism that governs neural plasticity, which suggests that synapses between neurons become strengthened when neurons have action potentials close together in time. The dentate gyrus is the only site of neurogenesis in the hippocampus, allowing for new cells to be born throughout an organism's life (Gage 2002). Theories and computational models of dentate gyrus suggest that these newborn neurons allow for the temporal separation of similar events that take place in similar contexts (Rangel et al. 2014).

CA3 has two types of reciprocal connectivity to allow its theorized function of pattern completion. CA3 excitatory pyramidal cells project heavily onto themselves forming what is known as the "longitudinal association pathway." These excitatory connections are believed to allow for heteroassociation, which is the ability to recall a complete representation or sequence only given a partial subset of the original (McNaughton and Morris 1987). CA3 pyramidal cells also project onto inhibitory basket cells which allow for recurrent inhibition.

## Place Cells and the Cognitive Map

O'Keefe and Dostrovsky discovered "place cells" in the hippocampus and published the results in 1971. They reported that about 10% of the cells they recorded from in the CA1 region responded to an animal's spatial position while facing a certain direction. This led O'Keefe and Nadel (1978) to develop a spatial theory of hippocampus building on the work of Tolman, suggesting that these neurons represented an allocentric "cognitive map" of the environment. Tolman developed a cognitivist account of purposive and goal-oriented behavior and suggested that motion through an environment could be represented

topologically allowing for the identification of "cognitive" maps. CA1 place cells have receptive field known as place fields, which correspond to an increased firing rate while the animal is in a certain position in the environment (O'Keefe and Nadel 1978). Neurons in the dorsal region respond more robustly to spatial relationships, while the ventral regions coded more for emotional and social stimuli. Head-direction cells, which respond to different positions of the head relative to the body of the animal, have been discovered in the septal presubiculum, entorhinal cortex, retrosplenial cortex, thalamus and mammillary nucleus (van Strien et al. 2009). McNaughton and colleagues suggest that the hippocampus is part of a system for path integration. This system involves the integration of place cells with head-direction cells in the presubiculum, cortex, and thalamus (McNaughton et al. 1996). The cognitive map also involves other more complex abstract spatial representations supported by circuits between hippocampus, parietal cortex, and retrosplenial cortex (Alexander and Nitz 2015).

The Morris water maze is a popular experimental paradigm used to test hippocampal dependent memory. In this task, a rat is placed in a large circular pool of milky or opaque water where there is a hidden platform that allows the rat to escape from the water. The rat initially explores the environment randomly until finding the platform, and after the rat climbs on top of the platform the rat is removed from the maze. When placed back in the water maze, given that there are no local cues indicating the location of the platform, the animal depends on its memory of the platform's location relative to the global environment (Morris 1984). It has been shown that animals with hippocampal lesions have significantly impaired performance on this spatial memory task.

## Hippocampal Rhythms: Theta and Sharp Wave Ripples

In rats and other animals, including rabbits, cats, and monkeys, the local field potential in the hippocampus is dominated by the hippocampal theta

rhythm, which is an oscillation that occurs at approximately 5–10 Hz. The local field potential is an electrical potential that is measured by embedding wires in the extracellular matrix of a group of neurons (Buzsaki et al. 2012). The theta oscillation increases in amplitude when the animal is moving throughout the environment and reduces when the animal is still. Hippocampal theta has been determined to be a dynamic wave that travels along the septotemporal axis of the hippocampal region (Lubenov and Siapas 2009). The origins of the theta oscillation are still unclear, but there is evidence to suggest that cholinergic cells in the medial septum might act as “pacemakers” for the hippocampal theta rhythm. The supramammillary nucleus of the thalamus with heavy connectivity to the septum is also a candidate for acting as a theta pacemaker (Buzsaki 2006). It is also possible that hippocampal interneurons play a role in regulating theta, as they are the only cell types that receive projections from medial septum, and also project from hippocampus to medial septum (Freund and Antal 1988).

CA1 place cells have been demonstrated to organize their action potentials to particular phases of the theta oscillation according to their temporal relationships. Phase precession is the phenomena where place cells coordinate their action potentials to different phases of the hippocampal theta oscillation representing where the animal currently is, where it is going, and where it has been (Buzsaki 2006). Models of hippocampal memory function suggest that this phase-dependent coding scheme might be a method for organizing memory encoding and retrieval (Hasselmo and Stern 2014).

Another rhythmic pattern in the hippocampal local field potential is the sharp wave ripple, which is a 140–200 Hz transient burst that occurs during wake and sleep (Buzsaki 2006). Hippocampal ripples have been observed in mice, rats, rabbits, monkeys, and humans (Logothetis et al. 2012). In awake animals, after running through a sequence of places tracked by place cell activity, when they stop running, sharp wave ripples occur. During those stop times, place cells fire in coordinated phase with the oscillatory ripples, in fact it was found that it was the same sequence of place cells rapidly firing in reverse temporal order

(Foster and Wilson 2006). It is believed that this sequential replay is a functional process which allows for memory consolidation.

## Temporal Coding

The hippocampus not only has a part in computing the animal's position in space but also information related to time. Lesions of the hippocampus can result in deficits in the recall of temporal order. In one task testing temporal order recognition, rats were trained to run through random sequences on an 8-arm radial maze. In the test phase, rats were presented with two arms simultaneously and were tasked with running through the arm which appeared earlier in the training sequence. Rats with lesions of the hippocampus performed poorly as compared to control rats on arms that were in close temporal proximity to each other (Chiba et al. 1994). CA1 place cells have also been observed to selectively fire to odors presented in a sequence. Similarly to the radial maze, the two temporally related odors were presented simultaneously and the rat was given a reward if it chose the odor that was presented earlier in the training sequence. This suggests that there are additional temporal dimensions that are coded along with the spatial mapping functions of CA1 place cells (Eichenbaum 2014).

## Conclusion

The hippocampus is a complex brain structure that carries out functions that are central to an organism's sense of spatial relations and memory formation. Future studies will be tasked with integrating the functional processes related to spatial maps and episodic events. Multiple studies have also been conducted where rats navigate a virtual reality environment, and it has been found that place cell activity is diminished to a significant degree (Aghajanian et al. 2015). Additionally, CA1 place cells have recently been shown to map onto more than just allocentric space. A recent study showed then when a rat was given a joystick to control an auditory signal, that CA1 place cells

mapped onto auditory dimensions suggesting that it might be necessary to broaden the definition of “place” with regard to “place cell” activity (Aronov et al. 2017). There are many questions to be answered about the relation between hippocampal function and structure, and will likely be the central focus of analyses for years to come with hopes to understand the representation of events, space, and time in the brain.

A conspicuous spatial regularity in the exploratory behavior of many organisms is the existence of a home site or home base. In the wild, animals have such a site to which they return regularly after exploring their home range or territory, be

they, e.g., ants, bumble bees, millipedes, small mammals, or wolves. In behavioral neuroscience experiments, the animal’s “home base” refers to its most preferred place, from which it performs excursions or forays into the environment (Eilam and Golani 1989). Upon being introduced into a novel laboratory arena, rats establish one or two places that stand out in terms of the time spent in them, the number of visits paid to them, and the incidence of grooming, and other behaviors that are typically performed in them, like crouching, turning in place around the forequarters, and the high frequency of rearing episodes performed in them. An accumulation of time through a high number of visits also characterizes the home base of, e.g., mice (Fonio et al. 2009; Benjamini et al. 2011), infant rats, and zebra fish (Stewart et al. 2010).

The conspicuousness of the home-base phenomenon begs an examination of its significance in spatial cognition. One common way of studying spatial cognition involves the study of maplike representations of physical space in the brain and the computational and neural analysis of navigational strategies involving different ways of information processing like piloting, dead reckoning, and the use of cognitive maps. The cognitive significance of the home base has been studied by using a complementary, ethological strategy, of obtaining a view on the organization of spatial cognition by studying the growth and differentiation of moment-to-moment spatial behavior (Gomez-Marin et al. 2016).

On a large platform placed away from walls, devoid of objects or markers, each individual rat will establish its own home base in a specific place, often at a corner but sometimes in the center area, in a location that is idiosyncratic to it. The selection of a location and the establishment of a home base in it thus reflect an endogenous constraint, characterizing the organization of exploratory behavior, independent, at least partly, of proximal features located in the environment. Home base location constrains cognitive spatial behavior.

The home base exerts its influence on the rodent’s behavior across the entire explored area. Visits to the home-base partition the path into

excursions in the environment. The latter are further partitioned into progression segments and lingering (staying-in-place episodes) (Drai et al. 2000). In rats, excursions initially consist in slow outbound and fast inbound portions, the outbound one comprising intermittent progression involving multiple lingering episodes (Tchernichovski et al. 1998). With repeated performance the velocity profile is reversed, as the outbound portion becomes fast and the inbound one slow and intermittent. The speed of progression has been shown to correlate in rats with how well-trodden (familiar) the path is, exhibiting faster progression on well-trodden paths. It has been claimed that the rodents maximize novelty signal-to-noise ratio during each excursion, where novelty is defined as the accumulated information gain. In this view, the rodents maximize novelty during outbound exploration and use novelty-triggered withdrawal-like retreat behavior, exploring the environment in a novelty-descending sequence. The piecemeal occupancy of a novel environment involving multiple repetitions of excursions characterized by incremental growth highlights how constrained behavior is during its morphogenesis. This contrasts with the view projected by mainstream studies of navigation, which study the maplike representations of physical space in the brain. These studies dispense with moment-to-moment morphogenesis and focus on full-blown behavior, at a stage when navigation appears to be relatively unconstrained. To become relatively free, spatial cognition requires, however, growth and differentiation.

The observation that the homeward trajectory of the excursion in rats is relatively straight and ballistic led to a series of studies, performed by Whishaw and colleagues, of lesioned animals, demonstrating a loss of that type of trajectory in the lesioned animals. This loss has been interpreted to indicate the use, in intact animals, of the dead-reckoning strategy during the inbound portion. It has been suggested that the lesioned part has been involved, when intact, in the computation of the inbound trajectory both in light and dark conditions. The brain structures claimed to be involved in computing the ballistic inbound trajectory included the hippocampus, the posterior cingulate

region, the fimbria-fornix, the posterior cingulate cortex, Ammon's horn and dentate gyrus, and the vestibular system (e.g., Wallace et al. 2006).

While growth and differentiation of the exploratory repertoire in intact rats imply more freedom, dopaminergic drug stimulation induces a cognitive shutdown of freedom: amphetamine (0.5–5 mg/kg Sc; Eilam and Golani 1994) and more so chronic treatment with the dopamine D2–3 stimulant quinpirole consolidate an increasingly smaller number of well-trodden routes along which increasingly shorter excursions are performed, and apomorphine (1.25 mg/kg Sc) disconnects behavior from locale space (Szechtman et al. 1985). The excessive, repetitive returns to the home base and the associated compulsive checking with quinpirole have been considered an animal model for obsessive-compulsive disorder (OCD; Szechtman and Woody 2004).

In intact mice, the growth in complexity of excursions is modular (Fig. 1), first enacting in an arena surrounded by a smooth wall of the terrain around the doorway (so-called garden); (zero-dimension space; <https://www.youtube.com/watch?v=Oc-JEn-j1xM>); then the borderline surrounding the arena consisting of monotonical outbound and monotonical inbound movement (one-dimensional space; [https://www.youtube.com/watch?v=rOHZC\\_qWkY](https://www.youtube.com/watch?v=rOHZC_qWkY)); then the inbound portion that becomes non-monotonical, incorporating the so-called shuttles on the inbound direction (<https://www.youtube.com/watch?v=ykGq3jNNiBw>); and then the radial dimension, away from the borderline and toward the center (two-dimension space; <https://www.youtube.com/watch?v=OqhHRCDD5nU>) and only then jumping up on the wall (three-dimensional space). A main feature of this process is the modularity of growth: the mice engage in building up one dimension at a time for extended bouts of behavior (Fonio et al. 2009). The fact that they enact space on a dimension by dimension basis suggests that space is composed of locally integrated “physiological dimensions,” which amalgamate into a functional unity. Modularity is thus a major built-in constraint on attention and cognition.

**Home Base, Fig. 1** The moment-to-moment actual genesis of deliberate exploration performed from a mouse's home cage that serves as a home base. The home cage is connected by a doorway to a large circular arena surrounded by a smooth wall. The developmental landmarks were exhibited in a specific BALB/c mouse – session performed across a 3-h period. The spiral proceeding from top to bottom, first in the left and then in the right column, presents the time series of 2-D locations on the path traced by the mouse. The enumerated figure inserts

show the 12 landmark motions that characterize the behavior, traced in red within the arena and on the spiral. Blue dots indicate instances in which the mouse approached the cage doorway and did not enter the cage (cage skips) or stopped short of returning all of the way home during a return (home-related shuttle). Absence of a blue dot implies departure into the home cage. Yellow path stands for the return portion within a home-related shuttle (Courtesy of Fonio et al. 2009)

Another major constraint, exhibited in rats but not in mice, is the initially slow and then fast increase in home-base attraction with every additional stopping episode, also expressed as the existence of an intrinsic upper bound on the number of stops. Once the upper bound is reached, the rat concludes the excursion and returns to the base without stopping, even when far away from the home base. In a large arena, rats extended inter-stop distances rather than crossing the upper bound on the number of stops per excursion (Golani et al. 1993). The same phenomenon has been observed by David Eilam in voles. This constraint implies some form of measurement performed by the animal in reference to the home base.

The connectedness (Saint-Hilaire 1822) exhibited between the home base, the excursions, the progression segments, and lingering episodes, and the outbound versus inbound portions, suggests that origin-related exploration might be homologous in vertebrates and perhaps also in arthropods (Cohen et al. 2015), sharing the same architectural plan of movement in allocentric space. The connectedness that unfolds at the kinematic level calls for a search for a corresponding connectedness at the neural level. If the measures are indeed homologous, then the likelihood of discovering a corresponding neural plan sharing a parallel connectedness will be increased. Such correspondence, however, has been investigated

to date mostly with regard to the inbound-outbound parts of excursions, suggesting the involvement of the hippocampus in mediating the structure of the inbound part of excursions (Wallace et al. 2006).

Understanding the organization of a living anatomical structure by studying its morphogenesis is standard in comparative anatomy (von Baer 1828). Since behavior, navigation included, is an extension of anatomy (Lorenz 2013), this also applies to navigational behavior. Measuring the morphogenesis of behavior in reference to the origin(s) used by the animal can thus reasonably be expected (Golani 2012). The home base is one such reference, shared by vertebrates and arthropods, and it is used during navigation. It would thus be expected that the home-base kinematic variables and their connectivity would be used as a search image in the pursuit of the key neurophysiological measures that support them. It would also be expected that these neurophysiological variables would be measured in reference to the animal's home base. In summary, home-base-related exploration constitutes a constrained process of origin-related growth and differentiation involving the emergence of freedom of movement along specified, modulated dimensions, reflecting a gradual emancipation of the animal's exploratory path from both endogenous and environmental constraints.

## Home Range

Luca Börger

Department of Biosciences, Swansea University,  
Swansea, UK

### Definition

A home range is an emergent space use pattern that results from animals restricting their movements within a certain area over a specific time period, while attempting to meet their needs for growth, survival, and reproduction. Home ranges are measured in units of area, or volume if altitude is taken into account, and time, and can be defined at different spatial scales, determined by the selected isopleth value of the utilization distribution.

### Introduction

All animals move, at least during some life-history stages, to obtain the resources for growth and survival, to reproduce, to escape from predators, etc. It is a common observation that most mobile animals repeatedly use the same area over time, instead of roaming over the entire available landscape, a behavior called site fidelity. Site fidelity leads over time to the emergence of home range patterns – a relatively small area (compared to the movement capacity of animals) repeatedly used by an animal over a specific period of time (Burt 1943; Börger et al. 2008). This type of behavior has fundamental consequences on evolutionary, ecological and behavioral processes, as individuals in a population do not mix but interact locally with a restricted set of individuals, which affects social interactions, habitat use, population density, population and meta-population dynamics, meta-community structure, spatial predator-prey dynamics, disease dynamics, etc. (Horne et al. 2020). Thus animal home ranges are an important focus of ecological and behavioral studies, yet at the same time the field has been

characterized by frequent and protracted methodological debates about how to estimate animal home ranges from animal location data (Fieberg and Börger 2012).

### Home Range Structure and Dynamics

Site fidelity is the defining characteristic of home range space use – if animals do not restrict their movements to a confined area over the time interval considered, one cannot speak of a home range. Consequently, if an animal moves within a home range, there should be temporal stability in the area used, with repeated visits to certain areas within the home range. Home ranges are emergent space use pattern and thus are not something directly selected for by animals (“today I will use 150 ha”); instead, they are a useful index or probe for quantifying and investigating animal movement and space use behavior. Home ranges and territories are strongly linked but determined by fundamentally different processes – home ranges are defined and estimated without reference to defense or advertisement or reaction to intrusion by neighboring individuals, only the presence of the individual is required; territoriality instead arises when individuals exhibit spatially oriented aggressive behavior, i.e., aggressive defense of a space containing limiting resources, thus a territory is estimated by delineating the location of defense events and the location of competing neighbors is needed to define the area of exclusive use (Burt 1943). A territory is always part of a home range – often smaller in size, or of equal size to the home range, as, for example, for some large carnivores (Börger et al. 2008). The movements of animals within a home range are typically not uniform and the structure of home ranges is often multi-nuclear, with one or more frequently used areas and centers of activity. The area of more frequent (or intense or concentrated) use is called the core area, and the area of the home range external to the core area is called the home range “periphery” (Fieberg and Börger 2012; Horne et al. 2020). Home ranges are dynamic spatial patterns, driven by temporal, spatial, and individual-level behavioral and

environmental processes affecting the movements of animals, and the size and structure of home ranges can change by several orders of magnitude within and between individuals across time and space (Börger et al., 2006b). Importantly, home ranges may not cover always the same area during the life of the individual, with animals moving between areas and hence leaving the old home range and setting up a new one (Burt 1943). Home ranges are also closely connected and often part of other space use behaviors, especially dispersal and migration. Migratory animals often stay in stable home ranges before and after migration; similarly, dispersal is a three-stage process, with dispersing individuals staying in a home range before and after the transient dispersal event.

### Estimating and Modeling Home Ranges

A home range is estimated from a regular sample of animal movements (Börger et al., 2006a), collected over a defined time interval (which is important to address issues such as autocorrelation, see Fieberg and Börger 2012), typically using GPS or VHF tags attached to animals. Before modeling or analyzing home ranges, it is important to verify that the animal was moving within a home range; this can be done using net squared displacement or variogram methods (Horne et al. 2020). Much debate in the field has centered about differences between different home range estimation methods, but these concerns can be comprehensively addressed by closely selecting the most suitable methods to address specific biological questions (Fieberg and Börger 2012), evaluating if the sampling regime used to collect animal movement data is adequate to answer the biological questions of interest and if differences between methods have actually a relevant impact on the inferences obtained or not (Börger et al., 2006a). It is also important to consider the broad range of approaches available to estimate and model animal home ranges, which goes well beyond diatribes about specific methods. Overall there are

three different approaches to model animal home ranges (reviewed in Börger et al. 2008) – mathematical modeling approaches, or mechanistic home range analysis; individual-based modeling approaches based on optimal foraging theory; and statistical modeling approaches – with a more unitary view of home range behavior emerging in the past decades across these once rather separate fields of enquiry. A central question addressed by mechanistic home range analysis is understanding the behavioral processes which lead to the emergence of stable home ranges from otherwise unbounded movements. Early models uniquely focused on the role of scent-marking behavior of territorial species, whereas more recent models have started to develop more generally applicable models, especially including the role of memory (Ellison et al. 2020). Optimal foraging-based home range and territory models focus on the role of resource distribution and movement costs within a cost-benefit approach (Sells and Mitchell 2020), with strong links to cognition and sensory ecology. Statistical modeling approaches focus on identifying and quantifying the dynamic scale-dependent processes which determine the size, structure, and variation of home ranges across space and time (Börger et al., 2006a), the overlap between home ranges (Winner et al. 2018), etc. To do so, modern approaches use location data to estimate the most likely probability density function of the home range and use this likelihood function to evaluate the contribution of different hypothesized drivers affecting the size and structure of the home range. Thus, instead of methods which provide only an outline of the home range boundary, modern approaches use statistical methods such as kernel density estimation (Fieberg and Börger 2012), as they provide an estimate of the relative frequency distribution within the home range area of an animal's location over time – this is called the utilization distribution function (UD) and can be thought of as a measure of the probability to encounter an animal in a certain area. UD values range between 0% and 100%, and the area enclosed by a line of constant UD value, called an isopleth line, provides measures

of home range and core area size – typically, 95% or 90% isopleths are used to delineate the home range (Fieberg and Börger 2012). Using multiple UD isopleth measures, closely linked to clear ecological questions, can markedly increase the biological inferences obtained Börger et al. (2006b). A more recent group of kernel density estimation methods, the autocorrelated Kernel density estimation (AKDE) home range estimators (see Horne et al. 2020 and references therein), includes the autocorrelation information in movement data and allows to correct for small effective sample size, irregular sampling in time of animal locations, and deriving robust home range overlap estimates (Winner et al. 2018). It is important however, when using these latter methods, to verify that the strong underlying assumptions of the AKDE approach are adequate for the data used and the questions addressed. If sufficiently frequently sampled movement data are available, further understanding can then be obtained by using newer methods which go beyond the utilization distribution and link home range analysis to methods used in movement path analysis, for example, directly allow to identify home range areas that are intensively exploited or repeatedly visited (Benhamou and Riotte-Lambert 2012), as well as using multi-sensor biologging methods (e.g., accelerometers, magnetometers, temperature and dive depth recorders, etc.) which allow to include further metrics, such as the type of behavior displayed at specific locations or the state of individuals.

## Conclusion

Animal home ranges are a central focus of research in ecology, animal behavior, and cognition, especially concerning the role of memory and sensory information. A very large set of methods and approaches can be used, and methodological advancements in the field are continuous. To make the most of this potential, it is important to focus on the biological questions and select the most appropriate set of methods and approaches. A new frontier in the field lies

also in including behavioral information into home range analysis, especially by using multi-sensor biologging methods.

### Definition

Homeobox genes are a group of similar genes having a common DNA sequence (a homeobox) responsible for coding a homeodomain. They play a vital role in governing the formation of bodily segmentation and cell differentiation during embryonic development.

### Introduction

A homeobox is comprised of a DNA sequence, around 180 base pairs long, and resides inside the genes governing the patterns of anatomical development (morphogenesis) in various organisms like plants, fungi, and animals (Gehring 1992). These genes were initially described in *Drosophila melanogaster* where they function as the master regulators of the various bodily segmentation and structures during the embryonic development process (Schofield 1987). They code for a string of 60 amino acids termed as homeodomain. An important feature of the homeobox genes is that they are present on every human chromosome, often appearing in clusters (Boncinelli 1997).

### The Homeodomain

Homeodomain is the part of the protein that attaches (binds) to specific regulatory regions of the target genes. This region is highly conserved, and the 60 amino acids are arranged in a

helix-turn-helix configuration. Interestingly, most homeodomain-containing proteins function as transcription factors, which means that they bind to and control the activity of other genes (Bürglin and Affolter 2016; Gehring 1992, 1993).

### Structure of the Homeodomain

The 60-amino-acid long chain of the homeodomain comprises of three alpha helices. Helix 1 and Helix 2 are joined together by a short loop, thus forming the HTH (helix-turn-helix) structure, whereas the third one is responsible for the direct interaction with DNA involving a number of hydrogen bonds, hydrophobic interactions, as well as indirect interactions via water molecules, occurring between the particular side chains and exposed bases of the DNA in the major groove (Schofield 1987).

### Sequence Specificity

Homeodomain proteins show a proclivity toward the DNA sequence 5'-TAAT-3'. However, non-specific binding has also been reported but it takes place with lower affinity. It binds with the B DNA with the aid of its C-terminal recognition helix, rich in lysine and arginine, which aligns with the DNA's major groove, while the N-terminus aligns in the minor groove (Carton et al. 1993).

### Classes of Homeobox Genes

Homeobox genes can be divided into a number of classes that have been shown along with their few examples in Table 1 below (Bürglin 2001; <https://www.genenames.org/>).

Among these, Hox genes are of high importance and have been explained in detail in the following section.

### Hox Genes

Human Hox genes are present in the four homeotic clusters, namely, A, B, C, and D

**Homeobox Gene, Table 1** Different classes of homeo-box genes with a few examples

| Classes of homeobox genes | Examples               |
|---------------------------|------------------------|
| Hox cluster genes         | Antp, ubx, ftz         |
| Dispersed Hox-like genes  | Ems, cad               |
| POU class                 | Unc-86                 |
| Prd class                 | Drosophila gene paired |
| Prd-like class            | Gene family Alx, Argfx |
| LIM class                 | ISL1, ISL2             |
| ZF class                  | ADNP, ADNP2            |
| Cut class                 | CUX1, CUX2             |
| HD zip class              | AIRE, ASH1L            |
| TALE class                | IRX1, IRX2             |
| Pros class                | PROX1, PROX2           |

located on different chromosomes. It is known that the genes of the different clusters work in cooperation in order to establish the identity of body segments along the head-tail axis. Each homeotic cluster further comprises of 13 genes as shown in Fig. 1. Hox genes are homologous in the entire animal kingdom implying that the nucleotide and the protein sequence along with their positions have a lot of similarity among most animals. This is because they were present in a common ancestor of flies, mice, and humans (Fig. 1). It is peculiar to observe that the genes located in the beginning are responsible for the development of the structures near the head region of the organism, whereas the genes located at the end are responsible for the development of the lower (or tail) end of the organism.

Biological Function

In the case of humans, the homeobox gene family comprises approximately 235 functional genes and 65 pseudogenes (Holland et al. 2007). In humans, they are known to be associated with a number of vital activities like the genesis of the different organs and limbs along the anterior-posterior axis, nucleocytoplasmic trafficking of Hox transcription factors, and cell differentiation. Homeoprotein transcription factors are responsible for switching on the

**Homeobox Gene, Fig. 1** Homology between mice and human Hox genes. A similarity is seen between the Hox gene expression in the body segments of both the mouse and the human as depicted by orange, pink, blue, and green shading. Provided by OpenStax CNX. (<http://cnx.org/contents/185cbf87-c72e-48f5-b51e-f14f21b5eabd@10.8>)

cascades of other genes. Some members of the Hox gene family are also known to be involved in vascular remodeling and angiogenesis by governing the changes in matrix degradation, integrins, and components of the extracellular matrix.

Additionally, some homeobox genes are also known to act as tumor suppressor genes, controlling the division of the cells in an uncontrolled way. As evident, Hox genes have diverse functions, and therefore, any mutation in these genes can cause serious manifestations and developmental disorders in the body. For instance, a mutation occurring in the HOX group of homeobox genes renders malformed limbs; in PAX group, it results in eye disorders, and in MSX group, it causes multiple abnormalities related to the head, face, and tooth. Further, as these genes also function as tumor suppressor genes, their mutation or changed expression can also lead to cancer (Zhao and Westphal 2002).

Conclusion

Homeobox genes code for a 60-amino-acid long homeodomain and are of utmost importance in the normal morphogenesis in animals including humans. The homeodomain region is highly

conserved across organisms indicating the important role played by them. They mostly function as transcription factors that act on the promoter region of their target gene. Mutation studies linked with the homeobox genes have demonstrated that any mutation in these genes can lead to serious abnormalities in different parts of the body. Studies based on the genetic engineering linked to the homeobox genes have shown great potential in the field of development of new organs from our own tissues. Henceforth, studies on these genes would unlock many embryonic development-related mysteries and aid in better treatment of the malformations and abnormalities occurring due to mutations in these genes.

## Homeostasis

Jacqueline Hill Tudor

Ohio University, Lancaster, OH, USA

## Introduction

**Homeostasis** refers to a relatively constant internal body state achieved by negative feedback mechanisms. French physiologist Claude Bernard (1813–1878) was the first scientist to propose that animals maintained a relatively constant internal state, regardless of external conditions. Bernard observed that animals have an ability to maintain a stable internal environment – *milieu intérieur* – even in stressful and harsh environments. He discovered that animals subjected to cold weather respond with vasoconstriction (narrowing) of superficial blood vessels, which diverts blood to deeper tissues of the body in order to conserve heat. It took approximately 50 years for Bernard’s visionary concept to be studied further. The term “homeostasis” was coined by physiologist Walter Cannon (1871–1945) in 1926. In his book, *The Wisdom of the Body* (1932), Cannon postulated that the interior of the body is at “equilibria,” but the equilibria is maintained within a range rather than a discrete value. He proposed that deviations from equilibria are automatically met with a commensurate response that counteracts the change. Cannon further proposed that there are discrete mechanisms acting simultaneously or consecutively to achieve homeostasis; he noted that homeostasis does not occur by chance and is a part of organized, self-government (Cannon 1932; Davies 2016).

Another prominent scientist involved in the early study of homeostasis was Curt Richter, a psychobiologist at Johns Hopkins University. In his early work, Richter removed the adrenal glands from rats, disrupting sodium and potassium homeostasis. Richter noted that rats compensated for sodium loss by consuming hypertonic saline (Richter 1936a, b). He published similar studies regarding calcium homeostasis. Richter et al. observed that removing the parathyroid glands

from rats lead to the rats consuming more calcium in their diets (Richter and Eckert 1937). Richter’s contributions to the field of homeostasis were unique from Bernard’s and Cannon’s. Richter demonstrated that animals could compensate for shifts in a biological set point with behavioral changes. However, Richter only considered one element of the homeostatic regulatory mechanism: the ability to respond to a deviation. However, homeostatic regulatory mechanisms involve several different elements to achieve a steady state or equilibrium. Homeostatic control systems require the establishment of biological set points, detection of deviations from the set point that compare “input value” (or stimulus) to the established set point, activation of mechanisms to counteract deviations, and restoration of the biological set point.

Maintaining Homeostasis

Most biological variables are controlled within a range, not a specific value. For instance, the set point for normal body temperature is 98.6° F in humans. However, it is well-established that healthy humans oscillate around this set point, with temperature being slightly higher or lower at any given time. Because of the variability in biological set points, it is appropriate to consider the body in a state of **dynamic constancy** (VanPutte et al. 2014). Dynamic constancy means that most variables are controlled within a range, and some biological variables deviate from normal in the short term but are stable in the long term (e.g., blood glucose is high post-meal but returns to pre-meal levels over time). Additionally, an individual may be out of homeostasis for one biological parameter but not another. Therefore, a normal set point applies to *each* biological variable. Many biological variables, including ion concentrations, have different intracellular (inside of a cell) and extracellular (outside of a cell) set points (Table 1). Osmolality, pH, blood plasma glucose levels, plasma oxygen levels, and others (Table 2) are also maintained around a set point, but the “normal” levels may vary depending on body compartment or other state-dependent factors (fasting vs. non-fasting). Loss of homeostatic

**Homeostasis, Table 1** Homeostatic levels of biologically important ions in humans

| Ion   | Extracellular concentration (in millimolar) | Intracellular concentration (in millimolar) |
|-------|---------------------------------------------|---------------------------------------------|
| Na+   | 145                                         | 15                                          |
| Ca2+  | 1.2                                         | 10 <sup>-7</sup>                            |
| K+    | 4.5                                         | 120                                         |
| Cl–   | 116                                         | 20                                          |
| HCO3– | 25                                          | 16                                          |

**Homeostasis, Table 2** Fasting blood levels of important biological variables in humans (Fox 2016; Padilla 2018)

| Biological variables | Normal range        |
|----------------------|---------------------|
| Arterial pH          | 7.35–7.45           |
| Oxygen               | 17.2–22.0 ml/100 ml |
| Proteins             | 6.5–8.0 g/100 ml    |
| Glucose              | 75–110 mg/100 ml    |
| Free amino acids     | 3.3–5.1 mg/100 ml   |
| Triglycerides        | < 250 mg/dL         |
| Hemoglobin           | Females: 12–16 g/Dl |
|                      | Males: 14–17 g/dL   |
| Osmolality           | 290 mOsm            |

control can result in death or disease of an organism. Many clinical biomarkers detect deviation from the normal set point and are used in the diagnosis of infection and disease.

Biological homeostasis is largely achieved by the use of negative feedback loops. The concept of negative feedback was first proposed by engineer and mathematician Norbert Weiner (Weiner 1948). Negative feedback loops are those in which a change (deviation from set point) is detected and an action is taken that opposes the change. Homeostatic regulatory systems utilizing negative feedback are comprised of several different components. First, a change (stimulus) must be detected by a **sensor** that measures the biological parameter. The information about the change must be compared to a set point by an **error detection** system. The error detection step compares the measured stimulus (an “input value”) to an established set point. By comparing the stimulus and set point, the **control center** of the regulatory system evaluates if action needs to be taken. In the event that the input value and set point are

not within an acceptable range of similarity, **effectors** are directed by the control center to evoke a response that opposes the action of the stimulus (Modell et al. 2015). In the case of human thermoregulation, thermoreceptors in the skin act as sensors to detect changes in temperature. Thermoreceptors convey temperature information to the hypothalamus by way of afferent pathways. The hypothalamus is actively involved in thermoregulation; it establishes the set point for body temperature. The hypothalamus acts as both the error detector and control center in this example. In instances of low body temperature (97.6° F or lower), the anterior hypothalamus stimulates contraction of piloerector muscles, increasing energy expenditure and heat production. The hypothalamus, which also serves as an autonomic regulator, stimulates the sympathetic nervous system to vasoconstrict cutaneous blood vessels. Peripheral vasoconstriction diverts blood to deeper body tissues, preventing heat loss (Hall 2016; VanPutte et al. 2014). In this example, the sympathetic nerves, because they provide motor output from the CNS and mediate the effects, act as effectors. It is important to note that the set point in a homeostatic control system can change depending on the body's biological priorities. In instances of infection, the hypothalamus can change the body temperature set point to a higher value, thus eliciting fever (Saladin 2017). An elevation in body temperature can slow microbial growth and allow the immune system to better combat the infectious agent (Willey et al. 2017).

## Homeostasis and Adaptation

Although homeostasis is a phenomenon that is universal in living organisms (even unicellular organisms), the organismal strategies used to maintain steady state are remarkably diverse. Many organisms have adapted to their environments through generations of natural selection in order to survive and thrive within their niche. For example, modern day Tibetans, who live in high altitude/low oxygen environments, are resistant to hypoxic (low oxygen) conditions that would harm humans living at sea level (Petousi and Robbins 2014). Such resistance to hypoxic conditions is

likely the result of natural selection. However, many organisms possess the ability to rapidly change homeostatic set points in a changing environment or regulate in some other way. Humans (even non-Tibetans) will very rapidly compensate for low oxygen levels by increasing rate of ventilation (Grover 1965); this is a classic example of negative feedback.

Not every animal maintains homeostasis the same way in a changing environment. Animals may be placed into one of the two categories: *regulators* or *conformers*. Conformers, such as starfish, match their internal body conditions to that of the external environment. Conformers can change the homeostatic set point in the presence of variable environmental conditions. For example, when *Asterias* (starfish) are placed in a high salinity water solution, they will increase body fluid salinity until they reach equilibrium with the external environment (Randall et al. 2002). For this reason, they are called *osmoconformers*. Osmoconformity is a useful strategy for many marine creatures that negates the need for them to absorb or expel water as they navigate waters of varying salt levels. Regulators use physiological or behavioral means to regulate internal body systems but do not change the internal set point in variable environmental conditions. If placed in a high salinity fluid, an osmoregulator's body fluid will stay below the concentration of fluid in the external environment. If an osmoregulator is placed in a low-salinity fluid, its body fluid will remain more concentrated than the external environment. Although many exceptions exist, most vertebrates are regulators and most invertebrates are conformers. Decapod crustaceans and some insects and mollusks are regulators (Randall et al. 2002). Thus, some organisms (including humans) actively work to maintain internal constancy, while others (such as starfish) change the biological set point to match external conditions, thus achieving equilibrium.

## Redundancy of Homeostatic Regulatory Mechanisms

If a particular biological variable is essential to survival, there are likely multiple feedback loops

involved in its regulation. For instance, blood pressure regulation in humans is achieved by multiple feedback loops and regulatory mechanisms. The heart is a circulatory system structure that pumps blood to and drains blood from the cells and tissues of the mammalian body. The heart is comprised of cardiac muscle tissue. In a state of systole (contraction), the heart pumps blood into arteries with a great deal of force. Blood pressure (BP) is a measure of the force blood exerts against blood vessels walls. Arterial blood pressure is a function of cardiac output (i.e., how much blood the heart pumps in 1 min), blood vessel elasticity (i.e., blood vessels with high elasticity distend and absorb force better than those with low elasticity), blood vessel diameter (i.e., dilated vessels have lower pressure while constricted vessels have higher pressure), and blood volume (i.e., volume and pressure are directly proportional). Normal adult blood pressure is approximately 120/80 mmHg, where 120 mmHg is the systolic (contraction) pressure and 80 mmHg is the diastolic (relaxation) pressure. Low blood pressure (hypotension) can lead to decreased blood perfusion to important organs, while high blood pressure (hypertension) puts small blood vessels at risk of aneurysm and the kidneys at risk of damage to the filtration membrane of the glomerulus. The circulatory system is responsible for nutrient delivery, waste removal, and gas transport to body cells; thus, significant deviations in blood pressure can be dangerous for multiple organ systems. Maintaining blood pressure homeostasis requires a multiorgan/system approach.

Blood pressure is detected by stretch **sensors**, called **baroreceptors**, located in the walls of two large arteries carrying blood away from the heart: the aorta and common carotid (Fox 2016). The baroreceptors respond to stretch signals and act as **sensors** of the blood pressure homeostatic control system. In instances of low blood pressure and low arterial stretch, the baroreceptors respond by firing action potentials at a lower-than-normal frequency. In instances of high blood pressure and high arterial stretch, the baroreceptors respond by firing action potentials at a higher-than-normal frequency. The electrical signals from the baroreceptors are conducted to the central nervous system by way of the glossopharyngeal and vagus nerves. The

glossopharyngeal and vagus nerves project to the nucleus tractus solitarius (NTS) located in the medulla oblongata. The medulla oblongata is part of the central autonomic network (see “► [Vasal-Vagal Stimulation](#)” entry) involved in regulation of the parasympathetic and sympathetic nervous systems. In this instance, the medulla oblongata acts as **error detector** and **control center** of the blood pressure control system. The medulla will interpret the signals sent by the baroreceptors. *If the deviation is low blood pressure*, autonomic centers of the medulla activate the sympathetic nervous system (aka “fight-or-flight” division of the peripheral nervous system); thus, the sympathetic nervous system serves as an **effector**; parasympathetic activity is reduced in instances of hypotension. The sympathetic nervous system innervates the heart pacemaker and myocardium, arterioles (small arteries), and veins. The sympathetic nervous system releases norepinephrine onto the heart to increase heart rate and force of heart muscle contraction. These effects raise cardiac output and blood pressure. Additionally, the sympathetic nervous system triggers vasoconstriction of arterioles (increasing peripheral resistance) and veins (increasing cardiac output) via the actions of epinephrine and norepinephrine. Thus, the net effect of sympathetic stimulation is an elevation in blood pressure which counteracts the original stimulus (low BP). *If the deviation is high blood pressure*, autonomic centers of the medulla activate the parasympathetic nervous system (aka “rest-and-digest” division of peripheral nervous system); thus, the parasympathetic nervous system serves as an **effector**. The parasympathetic nervous system innervates the pacemaker of the heart by way of the vagus nerve. The vagus nerve releases acetylcholine onto the SA and AV nodes, decreasing heart rate and cardiac output. A reduction in cardiac output decreases blood pressure (Chopra et al. 2011). Stimulation of the neurally mediated blood pressure regulation system will cease when the baroreceptor firing pattern reflects that of normal pressure conditions for that individual. Control systems regulating important biological variables such as blood pressure often contain multiple sensors, error detectors, control centers, and/or effectors.

The endocrine system produces several hormones that target the kidneys to help eliminate

excess fluid or retain fluid; some of the endocrine system's hormones regulate ionic (electrolyte) homeostasis, as well. Because of their roles in fluid balance, the endocrine and urinary systems are important in blood pressure regulation. Aldosterone is the “salt-retaining” hormone produced by the adrenal cortex. Aldosterone is released from the adrenal cortex when blood pressure drops, blood  $\text{Na}^+$  levels fall, or blood  $\text{K}^+$  levels rise. Aldosterone acts in the kidneys to reabsorb  $\text{Na}^+$  into the blood for retention and secrete  $\text{K}^+$  into the urine for elimination. As  $\text{Na}^+$  moves into the blood, chloride and water follow and are retained by the blood. As water moves into the blood, blood volume and blood pressure rise. Aldosterone secretion ceases when blood pressure and electrolyte levels return to the homeostatic set point (Saladin 2017). Angiotensin is a hormone whose production is triggered by a decrease in blood pressure (Saladin 2017). The active form of angiotensin, called angiotensin II, acts at both central and peripheral sites to restore blood pressure. Angiotensin II triggers widespread vasoconstriction, raising blood pressure. It also acts in the hypothalamus to stimulate a thirst sensation which encourages fluid intake. Fluids consumed will be absorbed from the gastrointestinal tract into the bloodstream, raising blood volume and pressure. Antidiuretic hormone (ADH), or vasopressin, is produced in the hypothalamus and stored in the posterior pituitary gland. During dehydration-induced (low blood volume; high blood osmolarity) hypotension, ADH is released from the posterior pituitary into the blood stream. ADH acts in the collecting duct of the kidney, stimulating the production and installation of aquaporins (water channels) (Boron and Boulpaep 2012). As aquaporins are installed, more water is reabsorbed back into the blood, restoring normal blood volume and blood pressure. Atrial natriuretic peptide (ANP) is produced by the atrial myocardium of the heart. ANP is released into the bloodstream when systemic blood pressure is high. It uses two main strategies to lower blood pressure. First, ANP increases urine production in the kidneys (increases blood flow to kidneys and attenuates reabsorption of  $\text{NaCl}$  and water); more water is eliminated via

the urine. Second, ANP inhibits the secretion of aldosterone, angiotensin, and antidiuretic hormone (all of which raise blood pressure). By inhibiting hormones that raise blood pressure, systemic blood pressure will fall (Hall 2016). Paracrine (local) mechanisms for blood pressure control also exist; cells within the walls of blood vessel can secrete chemicals which regulate blood pressure (Hickey et al. 1985). The blood pressure homeostatic control mechanisms outlined in this entry illustrate the truly complex nature of maintaining internal biological constancy. Other important biological variables, such as acid-base balance, have equally elaborate control mechanisms. Like blood pressure homeostasis, acid-base homeostasis involves multiple organ systems, including the urinary, respiratory, and skeletal systems.

## Introduction

Hominids are the group of primates known as the great apes, which includes orangutans (Tapanuli, *Pongo tapanuliensis*, Sumatran, *Pongo abelii* and Bornean, *Pongo pygmaeus*), gorillas (Western gorilla, *Gorilla gorilla*, and Eastern gorilla, *Gorilla beringei*), chimpanzees (*Pan troglodytes*), bonobos (*Pan paniscus*), and humans (*Homo sapiens*). The following chapter will address some of the most prominent cognitive abilities assessed among nonhuman hominids, addressing both physical and social cognition and where the two domains intersect. This will be followed by a discussion of how cognition is linked to behavior, particularly with regard to social behavior. The covariation between cognitive abilities and behavioral traits will then be addressed, considering indications that both share the same underlying mechanisms.

## Hominid Cognition: What Is Known So Far

Among nonhuman apes, two broad cognitive categories have been defined – physical cognition and social cognition. Physical cognition is defined as the ability to deal with the physical environment, through locating, selecting, and extracting food (Herrmann et al. 2007). To forage successfully, individuals must be able to deal with space, quantity, and causal reasoning, the latter referring to the relationship between, for example, a tool

(the cause) and the retrieving of food (the outcome). Social cognition on the other hand deals not with inanimate objects but with the social environment. Social skills are imperative to group living, enabling an individual to form bonds which are crucial to receiving social support during disputes. Social cognition allows individuals to balance competition and cooperation in a group, through learning from, manipulating, and predicting behavior of others (Herrmann et al. 2007). To achieve these goals, social learning, communication, and perception are key.

The Primate Cognition Test Battery (PCTB) is a series of tests that encompass both physical and social cognitive ability in great apes (Herrmann et al. 2007). These tests range from assessing spatial memory, quantity discrimination, and tool use to tasks which require problem-solving by observation, following cues to find a hidden reward, and understanding intentions. The extent to which different species perform on these tasks varies. Chimpanzees perform better than orangutans, but similar to human children, on tasks assessing physical cognition. Contrastingly, chimpanzees and orangutans perform about the same on social cognition tasks, which is significantly lower than the performance of children (Herrmann et al. 2007). When chimpanzees are compared with their closer cousins, bonobos, there is overall little difference in performance in either domain; however notably, chimpanzees outperform bonobos on tool use tasks, whereas bonobos are more successful than chimpanzees on tasks assessing Theory of Mind (Herrmann et al. 2010), that is, the ability to understand the perspective, intentions, or feelings of another. Such differences likely derive from the immediate environmental demands of each species. Chimpanzees experience higher resource competition than bonobos, which could make extractive foraging skills advantageous in an environment where food is harder to come by. Bonobos on the other hand experience a more socially tolerant society, which is likely to provide selection pressure for empathetic and perspective-taking behaviors.

While it appears that there are cognitive similarities throughout the great apes, species variation in cognition could be attributed to differences in social systems. Species that exhibit fission-fusion dynamics, where group composition

changes continuously, have been found to perform better on tasks testing inhibition, such as through foregoing a smaller reward to wait for a bigger one (Amici et al. 2008). In these tasks, chimpanzees, bonobos, and orangutans outperformed gorillas. This supports the theory that living in a socially unstable environment is associated with more behavioral flexibility and, importantly, highlights that social structure rather than taxonomy should be considered when understanding species differences in cognition. An additional point to consider is that, while tests such as the PCTB treat physical and social cognition as distinct entities, group living often requires that these two domains be employed simultaneously. Indeed, data from 62 primate species (including chimpanzees, bonobos, the Bornean orangutan, and the Western gorilla) found that traits of both physical and social cognition are highly correlated, suggesting coevolution of different intelligence domains (Reader et al. 2011). To better understand how social and physical cognition intersect one another and to understand the behavioral and ecological relevance of these cognitive domains, it is necessary to consider their application in not only a captive but also a wild context.

## Hominid Behavior: Links to Cognition

In terms of physical cognition, behavior is important in understanding how individuals deal with their environment. For example, without observing tool use in wild chimpanzees, there is no way to understand the ecological relevance of observing spontaneous tool use in a captive population. The way in which a tool is chosen, manipulated, and applied can provide insight into the underlying cognitive processes. If an individual is observed cutting or stripping a stick to make it shorter or sharper for a particular purpose, it could be said that they understand the causal relation between a particular tool type and a given food source. An understanding of cognitive abilities is thus very dependent on observational studies and, furthermore, measuring behavioral responses.

Captive studies now indicate that chimpanzees, bonobos, and orangutans do seem to have a concept of false belief, which has long been considered

to be a uniquely human aspect of Theory of Mind. Buttleman and colleagues (2017) found that the apes behaved similarly to 16- and 18-month-old human children in a helping task that required them to understand that the experimenter had a false belief about the location of an object. The apes were more likely to correctly locate the object for their human counterparts in the false belief trials compared with trials when the experimenter knew where the object was or was generally ignorant about the location of the object. While such studies are pivotal in understanding and defining ape cognition, especially in comparison to humans, an understanding of concepts such as Theory of Mind is not complete without studies from wild populations. For example, chimpanzees have been found to warn naïve group members of potential danger (a planted model snake) when they are aware that the group member is unaware of the danger (Schel et al. 2013). The fact that alarm calls were directed to the arrival of friends, and only stopped when new arrivals observed the snake, suggests that wild chimpanzees can understand what conspecifics do and do not know and that they can use communication intentionally to alter the behavior of conspecifics. Such a finding suggests that perspective-taking is evident in wild chimpanzees and is not simply an artifact of captivity. This is also a key example of how physical cognition (knowledge of potential danger) and social cognition (communication about the potential danger) are integrated into group activity and individual behavior.

One problem with studying the relation of behavior to cognition is that the overlap between the two is sometimes hard to define. For example, empathy can be a part of cognition in the form of perspective-taking, such as “putting oneself in someone else’s shoes”; but it can also be as basic as a physiological response, as in the form of emotional contagion, a response that completely bypasses the need for cognitive input (de Waal 2008). Helping behavior is also considered a form of empathy, another example of where cognition and behavior intersect. Chimpanzees will give a tool to a requesting conspecific, if they do not need the tool themselves (Yamamoto et al. 2009), thereby understanding the request of the conspecific (social cognition) and the purpose for

which the tool is required (physical cognition) and choosing whether or not to act on that understanding (behavior).

In addition to aiding an understanding of cognitive abilities observed in captivity, studies from the wild highlight the importance of studying behavior and cognition in parallel. Like different cognitive domains, the two do not operate independently. The current understanding of ape cognition is based very much on evidence from captivity, where controlled experiments such as Theory of Mind tests and test batteries are easier to conduct. Yet the continued study of wild behaviors, such as localized differences in tool use, social learning, helping behavior, and social knowledge, is informative in understanding the origins of cognitive abilities.

## Underlying Mechanisms of Cognition and Behavior

In general, observing behaviors informs two diverging questions: (1) with regard to species differences and (2) with regard to individual differences. The consideration of species differences has already been highlighted above. This section will therefore focus on individual differences.

Since the days of Darwin, observers of behavior have noted that the behavior of any given population may be variable. Where some individuals are shy, others are bold. Where some are aggressive, others may be fearful. The question thus is not whether behavioral variation exists, but why it exists. Behavioral ecologists have argued that variation in the population is required for natural selection to act, and is the basis for, rather than a product of, natural selection. It is now becoming clear that in a socially complex group, there is not one optimal strategy and that individuals produce consistent patterns of behavior across time and context which can differ from other group members. In recent years, a stronger focus has fallen on understanding individual differences in behavioral variation, which is now often framed in terms of “personality.”

Assessing personality is informative in cognitive terms to understand why some individuals succeed at tasks where others fail or why some

individuals are motivated toward a given task where others lack interest. Assessment of individual differences is also informative to understanding the links between cognition and behavior. While the study of behavior is of particular relevance to the understanding of cognition, behavioral traits may also covary with attention to or performance on particular tasks. Captive chimpanzees rated by keeper questionnaires as being high on openness, a component comprising traits such *inquisitive* and *inventive*, were found to be more consistently engaged in a series of touch screen tasks that assessed aspects of physical cognition (Altschul et al. 2017). Individuals with higher conscientiousness scores (not *reckless*, not *distractible*) also participated in these tasks more often and were less likely to drop out than low-conscientiousness counterparts. These and similar findings are indicative of underlying shared mechanisms that contribute to variation in cognition and behavior. Assessing not only the links between cognition and behavior but also the possible mechanisms that contribute to their covariation – be it genetic, environmental, or epigenetic – is an important step in understanding intraspecific variation in cognitive abilities.

Interspecific comparisons of personality also allow an understanding of how species differ in behavioral variation and provide consideration of what differences in selection pressures could have resulted in these trait differences. For example, it is hypothesized that the complexity of fission-fusion societies, as found in chimpanzees, bonobos, orangutans, and humans, has led to separate dimensions of agreeable and extraverted traits, compared with gorillas, who live in tight family units and exhibit a single dimension of sociable traits (Eckardt et al. 2014).

These studies highlight the role that personality assessment can play in understanding not only intraspecific variation in cognition but also a comparative understanding of cognition and behavior among the great apes. Combined with observations in the wild and cognitive tasks implemented in captivity, personality assessment provides a third dimension to the understanding of great ape cognition.

## Conclusion

This chapter highlights the different aspects of hominid physical and social cognition, their overlap and links to behavior, and finally the importance of considering individual differences when studying behavior and cognition. It is important to note that this is in no way a thorough assessment of the literature and provides simply an overview which should allow readers direction should they wish to learn more on these topics. It is also noteworthy to add that, while the study and knowledge of hominids is growing, much of this research is biased toward chimpanzees, likely due to their larger group sizes which are more suited to research. The comparative perspective would certainly benefit from more cognitive research in gorillas.

## Introduction

This chapter will be similar in structure to the chapter on hominids, with the exception that it will focus on the similarities and differences in

physical cognition, social cognition, and behavior between the great apes (hominids) and all apes (hominoids) which includes the addition of the lesser apes, gibbons (Hylobatidae). Current phylogenetic understanding of the gibbons proposes that there are 4 distinct genera, *Hoolock*, *Symphalangus*, *Nomascus*, and *Hylobates*, and up to 20 distinct species (Fan et al. 2017). Despite such diversity, comparative assessment of cognition has focused primarily on the great apes, and there is much still to understand about hominoid cognition as a whole. Yet the behavioral differences between gibbons and their great ape cousins could provide a better basis for the phylogenetic understanding of the variation in cognitive ability. This chapter will touch on the need to understand environmental influences that may have provided selection pressures for particular cognitive abilities, such as habitat, group size, and social structure. Such an understanding could be influential in addressing differences in ability across the primate phylogeny.

## Gibbon Cognition: Are Lesser Apes Lesser?

As the taxonomic link between hominids and Old World monkeys, the study of gibbon cognition is key to understanding the evolution of both physical and social cognitive abilities among primates. Comparisons on the Primate Cognition Test Battery between apes (chimpanzees and orangutans) and Old World monkeys (long-tailed macaques and olive baboons) reveal that cognitive differences between the two clades are perhaps not as vast as has been suggested (Schmitt et al. 2012). Comparisons revealed parallels in performance across species in tasks assessing physical and social cognition, the primary difference being in the monkeys' lower performance than apes on causal reasoning tasks, such as using a tool to obtain a reward (for more details see chapter "► Hominid"). Given this indication of domain-level similarities in monkey and great ape cognition, it is interesting to consider where the gibbons or "lesser" apes fit into this picture.

The following section will consider this picture in more detail.

Assessed on a task that examined their ability to demonstrate flexible learning, gibbons (*Hylobates*, *Symphalangus*, and *Hoolock*) failed to transfer knowledge from one learned association to another, something that has been demonstrated in rhesus macaques and chimpanzees (D'Agostino and Cunningham 2015). Such an ability should simplify learning on a new but similar task to one learned previously. Despite not making the knowledge transfer quickly, gibbons from four different species were able to learn individual food color associations, with notable differences in learning rate between species. This latter finding may point to different environmental pressures in learning rate. For example, *Hoolock* gibbons, who live in a highly variable environment, learned faster than their *Hylobates* counterparts, whose access to food resources is more stable (D'Agostino and Cunningham 2015). While strong conclusions cannot be drawn regarding the relationship between learning in a captive group and its relation to natural selection pressures, these findings raise the question whether differences in environment, and not just phylogenetic similarities, should be considered when addressing comparative cognition.

A key aspect of physical cognition is the ability to use and manipulate tools to access food. On a task assessing tool use, captive housed hoolock gibbons (*Bunopithecus hoolock*) were able to use a rake to access a food reward, showing similar if not slightly better performance to a similar task done with chimpanzees and capuchins (Cunningham et al. 2006). While this finding suggests that the gibbons may have had a causal understanding of the spatial relationship between the tool and the reward, the fact that some individuals performed below chance to start with and then improved their performance with time could also indicate associative learning. Observations of gibbons' use of tools are somewhat limited (Geissmann 2009), suggesting that either they do not commonly use tools in the wild or that observations and reports of gibbon tool use

are simply lacking. In one observation, it was suggested that a female white-handed gibbon (*Hylobates lar*) frequently used an enclosure door as a tool by incorporating the sound of a door slam into her "great call," a phase of a call sequence where the male and female form a duet (Geissmann 2009). Renowned for their call repertoires, it is perhaps key to understanding gibbon cognition to explore the role of communication in relation to their knowledge and understanding of both the social and physical environment.

Assessment of gibbon social cognition reveals, similar to the limited findings for physical cognition, that gibbons do not consistently compare with their great ape cousins. In an assessment of gaze following – an important prerequisite to perspective-taking behavior – gibbons of four different species (genera *Hylobates* and *Symphalangus*) did demonstrate gaze following in response to a human glancing upward, in a manner comparable to great apes (Liebal and Kaminski 2012). However, this finding did not hold when only initial looks were considered, that is, in first response to the experimenter, gibbons were generally more vigilant but did not necessarily follow their gaze directly. Unlike adult chimpanzees, the gibbons also did not habituate, i.e., change their response, as they became accustomed to the looking behavior of the experimenter. This suggests that their response was reflexive, rather than representing a more developed cognitive process, such as perspective-taking.

As discussed in the "► Hominid" chapter, perspective-taking has been demonstrated in a variety of ways in great apes. Given that an understanding of perspective-taking in other primate species could redefine the general definition of what it means to be human, it is a topic of heated discussion among primatologists. A topic of similar debate is that of self-recognition. Is a sense of self uniquely human, or do other primates possess a similar self-awareness that distinguishes them in their mind from others? There is strong evidence that chimpanzees, bonobos, and orangutans exhibit mirror self-recognition through the use of spontaneous self-exploratory behaviors in front of

a mirror. The evidence from gibbons, however, indicates otherwise. When faced with a mirror, members of three different gibbon species (*Hylobates*, *Symphalangus*, *Nomascus*) did demonstrate some self-directed behavior; however all failed to pass the mark test, i.e., to exhibit any behavior directed toward a mark made on the forehead, as has been observed in great apes (Suddendorf and Collier-Baker 2009).

These studies of social cognition indicate that there do appear to be differences in the perceptions of self and other between gibbons and great apes. In general, the limited evidence available on physical and social cognition in gibbons suggests that they do not compare with great apes' ability to perceive and manipulate their world. Whether this is a matter of phylogeny or of differences in selection pressures relating to social complexity remains to be seen: this shall be explored in the following section.

### Gibbon Behavior: Links to Cognition

To understand the selection pressures behind gibbon cognition, one should draw not only on the phylogenetic distance of Hylobatidae from humans and other apes but also on the environment in which they live. In addition to the variation in experience of environmental fluctuations among the Hylobatidae family, the social environment experienced by gibbons is contrastingly different to the fission-fusion groups of *Pan* and *Homo*, the multi-female harems of *Gorilla*, or the semi-solitary lifestyle of *Pongo*. Gibbons typically form pair bonds and live in family units with immature offspring, although these pair bonds are not necessarily lifelong, and extra-pair copulations have been known to occur (Palombit 1994). The gibbon duet is considered to be an indicator of pair bond strength: in captive siamangs, duetting activity positively relates to grooming frequency and behavior synchronization between mates, and negatively to distance between mates, which supports the notion that duetting may act to strengthen pair bonds (Geissmann and Orgeldinger 2000). Although

gibbon units experience emigration of offspring, and may also experience immigration of a new bond partner, the fluctuation in their social group is relatively less than experienced by the majority of their great ape cousins. With the exception of orangutans, group size of gibbons is typically smaller too. According to the social complexity hypothesis, group social complexity provides selection for higher cognitive ability, in order to keep up with the cognitive demand for maintaining an increasingly large social knowledge. The lack of such social complexity in gibbons could explain the apparent differences in cognition between the small and great apes.

There are however also behavioral similarities between these two clades. For example, a broad and variable repertoire of tactile and visual gestures has been observed in captive siamangs (*Symphalangus syndactylus*) (Liebal et al. 2004). While the context of these gestures often appeared flexible, some were used in similar ways to chimpanzees, such as the *wrist offer*, a submissive gesture, which was used by a subadult female siamang in response to aggression from her mother. The gestures observed also bore some similarities to those noted in monkeys, in that the siamangs used more tactile rather than visual gestures in social interactions (Liebal et al. 2004). By this evidence, the Hylobatidae seem to share aspects of both monkey and great ape communication. From here, a useful approach would be to draw links between social cognition and species-specific behavioral repertoires of gibbons, which would be informative to understanding the role of both social and environmental factors in cognitive ability.

An additional area of behavioral research that has been little addressed in gibbons is the assessment of individual differences. Like their great ape cousins, individual gibbons have been observed to vary in their interest in, boldness toward, and performance on cognitive tasks (D'Agostino and Cunningham 2015; Suddendorf and Collier-Baker 2009). There is, however, no apparent assessment of how these responses to test stimuli covary in some way with particular behavioral traits. Furthermore, a comparative

assessment of intraspecific behavioral variation between gibbons and great apes could help to establish patterns of trait commonalities across the hominoid family.

## Conclusion

The evidence presented in this chapter suggests that there is considerable variation in cognitive ability among the hominoids, with gibbons generally showing performance on physical and social cognition tasks that are not comparable with performance observed in great apes. While it is easy to hypothesize that these differences could be related to a reduced social complexity in gibbons, it is important to remember that cognitive and even behavioral studies conducted on gibbons are far fewer than for great apes. Furthermore, sample sizes are often too small to draw any definitive conclusions about species-wide ability (Liebal and Kaminski 2012). More urgent in the gibbon literature is the need to establish a clear phylogeny and to implement effective conservation measures for threatened species. Second to that comes the understanding of behavior or cognition. Yet a more detailed assessment of gibbon cognition, as well as its behavioral correlates, particularly in direct comparison to both great apes and Old World monkeys, would be greatly beneficial to a comparative understanding of primate cognition, and to what extent this is related to differences in environmental and social demands, or phylogeny.

## Definition

Patterns of movement observed in members of the Hominoidea superfamily.

The ape superfamily, Hominoidea, is a clade of Old World anthropoids (Catarrhini) (Fig. 1) that are native to Africa and Southeast Asia. In contrast to other primates, apes are tailless, wide bodied, and possess a wider range of motion at the shoulder joint. This greater degree of shoulder range of motion likely evolved as a result of arm-swinging (i.e., brachiation), which is the ability of animals to suspend and swing from tree to tree only using the forelimbs (Haviland et al. 2013). The Hominoidea superfamily consists of two families: Hominidae (great apes) and Hylobatidae (gibbons).

Gibbons, also known as “lesser apes” or “smaller apes,” are the most diverse extant taxa of Hominoidea. They are further classified into four genera: *Hylobates*, *Symphalangus*, *Nomascus*, and *Hoolock*. Unlike the Hominidae, gibbons are smaller in size and show minimal sexual dimorphism. They live in the subtropical and tropical rainforests of Southeast Asia, South China, Bangladesh, and Northeast India (Cunningham and Mootnick 2009). Gibbons are highly arboreal apes that are masters of brachiation. They are often

referred to as “acrobats of the forest” due to their ability to leap up to 8 m between branches with speeds reaching approximately 56 km/h (Cunningham and Mootnick 2009). Their alternate mode of locomotion on tree branches is bipedal, holding their extraordinarily long arms aloft for balance as they walk (Cunningham and Mootnick 2009). Additionally, gibbons are capable of quadrupedal climbing (Feldhamer et al. 2007).

Hominidae are the largest primates and exhibit strong sexual dimorphism, with males being larger than females (Feldhamer et al. 2007). The Hominidae family is composed of two subfamilies: Homininae and Ponginae. The Ponginae subfamily has one extant genus, *Pongo* (orangutans), with three extant species, all of which the International Union for Conservation of Nature (IUCN) currently lists as critically endangered (Ancorenaz et al. 2016; Nowak et al. 2017; Singleton et al. 2017). These Ponginae species are the Sumatran orangutans (*Pongo abelii*), Tapanuli orangutans (*Pongo tapanuliensis*), and Bornean orangutans (*Pongo pygmaeus*). Orangutans are large apes usually found living in lowland and hilly tropical rainforests. They spend most of their time in trees and their main mode of locomotion is brachiation and inverted quadrupedalism. Using their long arms, orangutans move slowly and travel great distances through the lower tree branches (Haviland et al. 2013).

Homininae, also called “African apes,” are further divided into two taxonomic tribes: Hominini and Gorillini. Homininae walk quadrupedally on their knuckles and are also capable of standing erect to walk bipedally (Haviland et al. 2013). The Gorillini tribe contains one extant genus: *Gorilla*. The gorillas are the largest in the Hominoidea species and are mostly found in the tropical rainforests of East and West Africa (Feldhamer et al. 2007). They are herbivores and spend most of their day eating plants (Haviland et al. 2013). Though primarily terrestrial, gorillas are capable of climbing trees and may even nest in them at night (Feldhamer et al. 2007; Haviland et al. 2013). In addition, male gorillas will also stand bipedally to perform their chest-beating displays (Feldhamer et al. 2007).

**Hominoidea Locomotion, Fig. 1** Cladogram of the extant Hominoidea: (a) Hominoidea superfamily; (b) Hominidae and Hylobatidae families; (c) Homininae and

Ponginae subfamilies; (d) Hominini and Gorillini tribes; (e) *Homo*, *Pan*, *Gorilla*, *Pongo*, *Hylobates*, *Symphalangus*, *Nomascus*, and *Hoolock* genera

Hominini has two extant genera: *Homo* and *Pan*. The genus *Pan* consists of two extant species: *Pan troglodytes* (chimpanzees) and *Pan paniscus* (bonobos). Both chimpanzees and bonobos are currently listed as endangered species by the IUCN. Moreover, in 2017 the Convention on Migratory Species selected the chimpanzees for special protection (Redmond 2017). Chimpanzees, also called “common chimpanzees,” “robust chimpanzees,” or “chimps,” are adapted for both arboreal and terrestrial locomotion. Their diet is composed of fruits, leaves, seeds, flowers, and meat (Feldhamer et al. 2007; Goodall 1986). Chimpanzees are widely distributed in sub-Saharan African forests and the savannah, with a tendency to build their nests over a wide area (Haviland et al. 2013). Bonobos, also called “pygmy chimpanzees,” are slightly smaller than common chimpanzees (Feldhamer et al. 2007). Bonobos are found exclusively in the rainforests of the Democratic Republic of Congo. In contrast to chimpanzees, they prefer to build their nests close to one another (Haviland et al. 2013). The bonobo’s diet is herbivorous, primarily consisting of fruits, leaves, seeds, flowers, and other plant matter (Feldhamer et al. 2007). Both chimpanzees and bonobos forage quadrupedally by knuckle-walking on the ground during the day and then return to the trees at sunset (Haviland et al. 2013).

Chimpanzees and bonobos are also capable of bipedalism, but this locomotor mode is less frequently used because the “bent-hip bent-knee” bipedal posture of these species is expensive energetically (Aiello and Dean 2002; Alexander 2004).

The genus *Homo* contains only one extant species, *Homo sapiens*, referred to as hominins or humans. The ability to stand upright and accommodate bipedal locomotion is a distinct feature of hominins, relying on the positioning of their body’s center of gravity directly over the area of the feet in standing position. Moreover, horizontal displacement of the center of gravity during bipedal locomotion is minimized by the structure and positioning of the femur, which results in a shorter lateral distance movement above the alternating stance legs (Aiello and Dean 2002).

## Major Locomotor Modes

The various modes of *Hominoidea locomotion* are specially adapted to navigate both the arboreal and terrestrial environments in which they live. During arboreal locomotion, one of the most common locomotor modes employed is climbing, most often on vertical supports. Vertical climbing is of vital importance to apes, as it is essential for

travel, escape, foraging, and seeking safe locations to rest (Cartmill 1985; Granatosky et al. 2019; Hanna et al. 2017). In primates, symmetrical gaits are mainly used to climb vertically if the diameter of the substrate (the tree) is smaller than the diameter of the body (Granatosky et al. 2019). These gaits utilize a lateral-sequence gait pattern (hindlimb followed by ipsilateral forelimb), during which the hindlimb serves as the primary support for the body weight and functions to propel the ape vertically throughout climbing (Hanna et al. 2017). Furthermore, while vertically climbing with symmetrical gaits, apes tend to move slowly with long intervals of grasping the substrate to maximize both their stability and security (Granatosky et al. 2019). However, asymmetrical gaits are most often used for vertical climbing when the diameter of the substrate is substantially larger than the diameter of the body, as the ape is forced to wrap itself around the substrate to ascend. In these gaits, each pair of feet (fore and hind) function more or less together and move at the same time or in couplets (Cartmill 1985; Hildebrand 1989).

Suspensory locomotion is perhaps the most common form of locomotion associated with the apes, despite the fact that such behaviors are rarely observed in African great apes beyond the juvenile stage (Granatosky 2016). Below-branch quadrupedal locomotion, also known as inverted quadrupedal locomotion, is common for the orangutans. During below-branch quadrupedal locomotion, the torso is pronograde (parallel to the ground) with both the forelimbs and hindlimbs used to hang beneath the substrate (the tree branch) and bear the body weight, loading the limbs in tension (Granatosky and Schmitt 2019; Stern 1975). Diagonal-sequence gait patterns (hindlimb followed by contralateral forelimb) are utilized and the forelimbs are the dominant weight bearing limbs, suggesting that this locomotor form may be a mechanical intermediate transition to another suspensory locomotor mode known as arm-swinging (Byron et al. 2017; Granatosky and Schmitt 2019).

Arm-swinging (also referred to as brachiation) is a form of forward movement where an ape hangs beneath the substrate and then advances

forward only using the forelimbs. This fluid motion appears to operate on the principle of the pendulum, in which energy is saved by switching between kinetic energy (movement of the body) and potential energy (height of the body) throughout the swing (Byron et al. 2017). However, these natural pendular motions only function as a way to reduce energy use (muscular involvement) in continuous-contact locomotion and very slow speeds. The complex three-dimensional arboreal environments in which arm-swinging occurs makes this simple pendular motion difficult to maintain for any appreciable distance. Instead the ability to maintain flexible locomotor cycling takes precedence over energy conservation (Byron et al. 2017; Fleagle 2013).

During both arboreal and terrestrial locomotion, apes utilize quadrupedalism as their most common locomotor mode (Granatosky 2018; Hunt et al. 1996). However, it is important to recognize that the primate quadrupedal gait is unique compared to the quadrupedal gaits of other mammals. Most other quadrupedal mammals tend to use lateral-sequence footfall patterns with a retracted humerus at forelimb touchdown and higher peak vertical forces on the forelimbs relative to the hindlimbs. Conversely, primate quadrupedal locomotion employs a diagonal-sequence footfall pattern with a protracted humerus at forelimb touchdown and higher peak vertical forces on the hindlimbs relative to the forelimbs (Granatosky et al. 2019; Granatosky and Schmitt 2019; Schmitt and Lemelin 2002). Apes, especially the gorilla and chimpanzee, often violate the diagonal-sequence diagonal-couplet pattern when walking on the ground and instead adopt lateral-sequence diagonal couplet gaits (Fig. 2).

African apes are unique in that they display a further specialization of quadrupedal locomotion known as knuckle-walking (Fleagle 2013; Schmitt et al. 2016). This form of quadrupedalism is favored as it is thought to reduce the finger bending loads of palmigrade and digitigrade postures (Schmitt et al. 2016). Knuckle-walking is differentiated from the other forms of quadrupedalism via the elevation of the palm and proximal phalanges above the substrate. The

**Hominoidea Locomotion, Fig. 2** “Hildebrand” plot displaying phase against hindlimb duty factor collected during quadrupedal walking in *Gorilla* and *Pan troglodytes* ( $n = 2$  species)

hand may be pronated or partially supinated with flexed intermediate phalangeal joints and neutral or slightly hyperextended metacarpophalangeal joints (Fleagle 2013; Schmitt et al. 2016). This places most of the body weight on the dorsal aspect of the middle phalanges, which are contacting the substrate. In a similar vain to reduce loads on the long digits, the orangutans have adopted their own unique form of quadrupedalism known as fist-walking. While fist-walking, the interphalangeal and metacarpophalangeal joints are flexed (making a fist) with the hand pronated or partially supinated and the thumb either touching the ground or not. This places the weight on the proximal phalanges as opposed to the middle phalanges as in knuckle-walking. If an orangutan is fist-walking either adducted or abducted (wrist deviated either radially or ulnarly), then the weight can be borne on the medial or lateral edge of the manus, on the thumb and medial edge of ray two, or on the lateral edge of ray five (Schmitt et al. 2016).

Although apes usually travel quadrupedally terrestrially and arboreally, almost all demonstrate some manner of bipedal tendencies (Alexander 2004; Hunt et al. 1996). Similar to arm-swinging,

walking bipedal gaits are dependent on the principle of the pendulum, or in the case of bipedalism, an inverted pendulum. Although this type of motion is able to conserve energy when walking, it does not do so during running. Nevertheless, elastic mechanisms are able to preserve energy during running because the kinetic and potential energy lost in the first half of a step is stored as elastic strain energy in stretched tendons and ligaments then released through elastic recoil in the second half of the step (Alexander 2004). The use of bipedalism in apes is rare, often demonstrated in the context of display or food acquisition (Alexander 2004; Richmond et al. 2001). In fact, 80% of chimpanzee bipedalism, most of which is postural, occurs during feeding. Bipedalism is favored over quadrupedal locomotion in this situation as it permits a higher reach into short trees and the ability to continuously gather fruit with both hands (Richmond et al. 2001).

The bipedal gait of apes, commonly described as bent-hip bent-knee walking, positions the trunk sloping forward and the knees strongly bent at mid-stance, placing the body’s center of mass in front of the hips. In this posture, the trunk is more erect than in quadrupedal walking and the knees must be kept anterior to the hips throughout the stance phase to ensure the force on the foot is vertical and in line with the center of mass. Furthermore, the longitudinal components of force on the ground allow the forward velocity of the center of mass to pass through a minimum while moving over the supporting foot, which keeps the resultant force on the foot in line with the center of mass. This is achieved by the foot pushing both forward and down while in front of the body to decelerate as well as support it and then pushing backward and down when behind the body to accelerate it. When moving bipedally, apes often take shorter strides than in quadrupedal locomotion and tend to utilize plantigrade locomotive postures (placing the entire foot on the ground) with the heel and lateral midfoot striking the ground at the same time (Alexander 2004) (Figs. 3 and 4).

In contrast, the human bipedal gait is often referred to as “striding.” This is largely attributable to the smooth means of traveling during

**Hominoidea Locomotion, Fig. 3** Differences in where the body weight passes during bipedal locomotion in (a) *Pan* and (b) *Homo*. Medial portion of both feet are on the left

(a)

(b)

**Hominoidea Locomotion, Fig. 4** Differences in the bipedal postures of chimpanzees and humans: (a) bent-hip bent-knee walking; (b) striding

which the energy output of the body is reduced to a physiological minimum (Sockol et al. 2007). While striding, humans weakly bend the knees at mid-stance, hold their trunk vertically and place the heel on the ground before any other part of the foot (Alexander 2004). The normal human walking cycle is separated into the stance phase when the foot is on the ground (further divided into heel strike, foot flat, mid-stance, and push or toe-off) and the swing phase when the foot is moving forward (further divided into acceleration, mid-swing, and deceleration). Although these phases operate simultaneously by alternating sides with the completion of each cycle, the human gait spends 60% of the time in stance phase. The center of gravity begins the cycle midway between the feet and anterior to the ankle joint, then moves in a posteroanterior direction toward the swing limb and before toe-off shifts it to the stance side where the weight is balanced to allow for forward propulsion of the swing limb. Moreover, during this cycle the body weight passes from the heel to the head of the fifth metatarsal and across the remaining metatarsal heads to the hallux (Fig. 3). This cycle is also accompanied by the regular motions of the shoulders, arms, and head, with the opposite arms and legs swinging in tandem. Arm movement in the anteroposterior plane reduces shoulder rotation keeping the head forward and balances pelvic rotation keeping the trunk straight (Schiowitz et al. 2005).

### Technological Innovation and the Evolution of Human Bipedalism

*Hominoidea locomotion* has long been an area of scientific interest, perhaps due to the wide range of locomotive modalities observed within the group and because of the common lineage shared between human and ape ancestors. Furthermore, understanding *Hominoidea locomotion* offers insight into the origin and evolution of human bipedalism, which can facilitate various technological advancements. One recent area of interest is the potential use of innate neuromotor circuits conserved across ape ancestors to treat human patients with locomotor impairments (Zehr et al. 2009).

Habitual bipedal locomotion is the defining characteristic of the earliest hominins and represents a critical divergence of humans from other ape lineages (Sockol et al. 2007). It was once believed that the inverted pendulum model observed in human bipedal walking was the result of a simple transition from quadrupedalism in a terrestrial ancestor. However, more recent experimental studies on human and nonhuman primate locomotion suggests that bipedalism evolved through multiple complex transitions that likely originated from a climbing, arboreal fore-runner (Schmitt 2003). Nevertheless, much uncertainty still surrounds the evolution of human bipedalism. One particular area that remains ambiguous is the mode of locomotion that the most recent human ancestors utilized (Fleagle 2013; Richmond et al. 2001; Stern 1975). Theories regarding the nature of locomotion of our most recent ancestor can be described using three main models: a terrestrial knuckle-walking model, a brachiation model from a small bodied suspensory ancestor, and a model based on a vertical climbing ancestor. Molecular data supporting the close phylogenetic relationship between chimpanzees and humans provides strong evidence for the terrestrial knuckle-walking model. However, there is still debate over whether or not bipedal locomotion offers a significant advantage in terms of energy conservation over quadrupedalism for the earliest hominids (Schmitt 2003; Sockol et al. 2007). To the contrary, recent experimental studies utilizing biomechanical models of climbing hominin ancestors suggest that, in terms of mechanical requirements, human bipedalism is more similar to arboreal climbing than terrestrial quadrupedalism. Nonetheless, it is likely that the earliest hominins displayed diverse locomotive modalities and that there is no single model that encompasses the gradual ten million year evolution of human bipedalism (Schmitt 2003). Scientific understanding of the hominin evolutionary timeline will continue to change as new fossil discoveries and technological advancements improve the ability to determine the species that are ancestral to humans (D'Août et al. 2014).

A crucial evolutionary model, in respect to treatment of patients with locomotor impairments,

suggests that bipedalism evolved as a result of arboreal foraging behaviors similar to those displayed by chimpanzees and orangutans (Fleagle 2013; Richmond et al. 2001; Stern 1975). More specifically, when these primates climb on branches seeking fruit, they simultaneously stand up, grasp a branch for support with one arm, and gather food with the other arm. While this may seem foreign, observing children on the playground “monkey bars” or watching infants pull themselves up when first learning to walk suggests otherwise. Recent research supports the idea that despite the different use of forelimbs during bipedal and quadrupedal locomotion, innate neuronal circuits coding for interlimb coordination and movement are preserved from our distant quadrupedal ancestors. Evidence from reflex studies in humans shows arm and leg coordination during the walking cycle that suggests the conservation of neuronal linkages for forelimb and hindlimb movements. With the help of novel technology, these innate reflexes can be used to facilitate the recovery of locomotor impairment in patients with motor deficits (e.g., after a stroke or spinal cord injury). Previous strategies used to treat neurotrauma patients focused on compensating for deficits and reconstructing damaged nerve fibers. However, emergent therapies are based on the concept that this innate neuronal network operates as the motor output for locomotion and can be exploited in rehabilitation post-neurotrauma. By activating the underlying neural circuitry linking the upper and lower extremities, the neural commands involved in rhythmic arm movement could facilitate locomotor retraining in the lower extremities (Zehr et al. 2009). Therefore, innovative rehabilitation technologies have the ability to advance towards using the intrinsic nervous system to assist in motor reprogramming.

One such innovation showing great promise in restoring mobility for severely paralyzed patients is the use of brain machine interfaces. These devices transmit neural inputs into commands that can be used to control artificial limbs, robotic wheelchairs, and similar external apparatuses. Brain machine interface technology relies on the premise that brain cortex function is preserved in a

spinal cord injury. This approach uses an artificial device to bypass the damaged spinal cord activity and enact voluntary motor intentions (Carmena et al. 2003). Experiments have shown promising results in nonhuman primates, including the ability of macaque monkeys to reach and grasp for virtual objects using a robotic arm as well as the ability to learn and navigate robotic wheelchairs with cortical activity as the primary control signal (Carmena et al. 2003; Rajangam et al. 2016). Thus, studying neuronal firing and locomotion patterns in both human and nonhuman ancestors is of critical importance for the future of neuroprosthesis.

## Conclusion

This chapter introduces the taxonomy of the Hominoidea superfamily and describes the major locomotor modes they utilize, which are vertical climbing, suspensory locomotion, quadrupedalism, and bipedalism. Suspensory locomotion and vertical climbing are important locomotor modes used by Hominoidea to navigate the arboreal landscape in which they live. The quadrupedalism of Hominoidea exhibits the distinctive features of primate locomotion and can be further specialized through the knuckle-walking of African apes or the fist-walking of orangutans. Hominoid bipedalism varies from the bent-hip bent-knee bipedal postures of chimpanzees to the habitual bipedal striding of humans. Careful observation and studying of these primary modes of *Hominoidea locomotion* has led to many hypotheses about the evolution of human bipedalism. The more recent data suggests that hominin bipedalism evolved through multiple complex transitions that likely originated from a climbing, arboreal forerunner. Furthermore, new research indicates that the innate neuronal circuits coding for interlimb coordination and movement are preserved from our distant quadrupedal ancestors, which may have important implications for the future of neuroprosthesis. Brain machine interfaces are one such ramification of this knowledge and may have the potential to restore body mobility

to paralyzed patients in the not too distant future. The future of Hominoidea locomotor research has much potential and deserves more attention, as it may one day produce lifesaving technologies that were once thought to be impossible.

## Hominoidea Morphology

Laura MacLachy, Emily Orlikoff and Miranda Nicole Cosman  
University of Michigan, Ann Arbor, MI, USA

## Synonyms

Anatomy; Ape; Evolution; Primate; Taxonomy

## Definition

Hominoidea is the taxonomic superfamily name for all living and fossil apes and humans. Hominoidea and Cercopithecoidea (the superfamily name for Old World Monkeys) together comprise the Infraorder Catarrhini.

## Introduction

The hominoids are a group of primates comprised of the smaller-bodied hylobatids (siamangs and gibbons, body sizes range from 5 to 12 kg) and the much larger hominids (great apes and humans, body sizes range from 33 to 175 kg) (Smith and Jungers 1997). The hylobatids are taxonomically diverse, with ~20 recognized species, but are restricted to the mainland and islands of southeast Asia and are generally similar to one another in terms of overall body plan, ecology, and behavior. For example, the hylobatids are all territorial and highly arboreal, form monogamous pair bonds, have high intermembral indices (much longer forelimbs than hindlimbs), locomote using brachiation (sequential manual suspension), and feed on fruit and leaves. The hominids are less diverse in terms of living representatives, with only four genera (*Pongo*, *Gorilla*, *Pan*, and *Homo*). However, each genus has distinctive patterns of social behavior, sexual dimorphism, substrate use, locomotion, and diet (discussed below). In terms of

geographic distribution, the hominids (with the obvious exception of *Homo*) are found in tropical forests of equatorial Africa (*Gorilla* and *Pan*) and southeast Asia (*Pongo*).

All nonhuman hominoids are united by a suite of functionally significant morphological features that distinguish them from other primates and other mammals. Many of the postcranial features are thought to be related to the challenges of engaging in arboreal travel and feeding at a large body size. For example, nonhuman hominoids lack a tail and combine a stable, orthograde (upright) trunk, broad torso, and widely spaced shoulders with relatively long forelimbs, high joint mobility, and strong pedal and manual grasping (Fig. 1). These traits allow them to engage in versatile locomotion in which their fore and hindlimbs can be differentially employed, such as during suspension and acrobatic and/or vertical climbing, permitting them to distribute their body weight across multiple supports as needed. But while the hominoid niche ancestrally includes the arboreal realm, the stable lower back and differential use of the fore and hindlimbs

**Hominoidea Morphology, Fig. 1** Posterior view of a chimpanzee suspending unimanually from a single branch (left) and anterior view of a chimpanzee climbing on multiple small supports (right). The arrows indicate distinctive hominoid features, including: no tail, orthograde trunk,

broad torso, widely spaced shoulders, long forelimbs, shorter hindlimbs, high hip and shoulder mobility, fully extendable elbow, and strong pedal and manual grasping. The chimpanzees are both wild *Pan troglodytes schweinfurthii* from Kibale forest, Uganda

have led some taxa (*Pan*, *Gorilla*, *Homo*) to also successfully exploit terrestrial habitats (e.g., through knuckle-walking and bipedality). Such locomotor versatility underlies the evolutionary “success” of all crown hominoids and was present to some degree in early fossil hominoids (MacLatchy et al. 2015).

In addition to having the largest bodies among the primates, hominoids also have the largest brains, both of which are implicated in their slow life history.

While humans are hominoids, and share many of these traits, this entry principally focuses on nonhuman members of the group.

## Morphology Overview

### Cranium

The cranium is responsible for housing the brain and sensory organs as well as for mastication and aspects of social communication. Its morphology represents a compromise of physiological function, phylogenetic history, and allometric scaling that together give rise to variation in the relative size and shape of different cranial structures (Bilsborough and Rae 2015).

The great apes possess prominent nuchal tori, and the African apes possess prominent supraorbital tori, serving to buttress and accommodate substantial muscular attachments (ibid.; Fig. 2). The great apes are also characterized by higher

cranial capacities compared to monkeys, reflecting their absolutely large brain size.

The African and Asian apes differ in several cranial attributes, including paranasal sinus morphology and the relative orientation of the orbits, palate, and basicranium. *Pongo* and the hylobatids lack ethmofrontal sinuses, which African apes and humans possess (ibid.). Additionally, *Pongo* and the hylobatids, although to a lesser extent, exhibit crania characterized by airohynchy, or an upward orientation of the palate and face relative to the basicranium (Fig. 2). By contrast, *Pan*, *Gorilla*, and *Homo* exhibit klinorhynch, or a downward orientation of the palate and face relative to the basicranium (ibid.).

Hominoids share in having a widened anterior palate, and hypertrophied incisor and canine roots (ibid.). Hominoids are also less prognathic than many other catarrhines, having a subnasal region that is flatter and less projecting; however, males in all large-bodied apes exhibit more subnasal prognathism than do females (ibid.).

The masticatory demands of hominoids vary, leading to differences in the relative size of chewing muscles and their points of attachment. *Gorilla* and *Pongo* have particularly robust attachments for the temporalis and masseter muscles on the lateral aspect of the vault (parietal and temporal bones), the zygomatic arch, and the vertical ramus of the mandible (Aiello and Dean 1990). Such traits are sexually dimorphic and will be described further below.

**Hominoidea Morphology, Fig. 2** Left lateral radiographs of *Gorilla*, *Pan*, *Hylobates*, and *Pongo* crania. Compare the deflection of the palate relative to the

basicranium in the African apes (klinorhynch) versus the Asian apes (airohynch). Scale bars are 5 cm

## Dentition

Hominoids generally retain primitive tooth morphology compared to other catarrhines (Fleagle 2013). Relative to monkeys, hominoids have broader incisors (*ibid.*), with frugivores (fruit eaters) having wider incisors than do folivores (leaf eaters). The canines in hominoids are wider, shorter, and relatively blunted compared to those of cercopithecoids. However, this pattern is less apparent in the hylobatids who possess relatively longer and thinner canines than those of the large-bodied apes. Humans have reduced canines with the upper canine having the same crown height as the upper incisors (Aiello and Dean 1990). Overall, compared to cercopithecoids, there is more variation in hominoid canine size, shape, and degree of sexual dimorphism (Fleagle 2013).

The premolars and molars of hominoids are relatively simple and unspecialized. The lower molars have an expanded talonid basin and the upper molars are quadrate in shape (*ibid.*). Hominoids differ in molar morphology according to diet, with folivores exhibiting longer shearing crests running between taller cusps, than do frugivores, as the crests facilitate breaking down leaves. Hominoids additionally have variable enamel thickness relative to their body size. *Pan*, *Gorilla*, and hylobatids have thinner molar enamel, *Pongo* has thicker enamel, and humans have varyingly thick enamel (Shellis et al. 1998; Smith et al. 2005).

## Postcranium

### The Vertebral Column, Thorax, and Pelvis

Like most mammals, apes have 7 cervical (neck) vertebrae; however, the thoracic region (chest) is typically comprised of 13–14 vertebral segments, an increase of 1–2 segments over most primates. The rest of the vertebral column of hominoids also differs from that of most other primates in terms of the number of vertebral segments in each region. The lumbar region (lower back between the chest and pelvis) is comprised of fewer segments (3–5), the sacral region (fused segments adjoining the pelvis) is comprised of more segments (4–6),

while the caudal (tail) vertebrae consist of a few, internalized segments (Pilbeam 2004). In contrast, other anthropoid primates, with the exception of a few New World monkeys, have longer lumbar regions (~7 vertebrae), shorter sacral regions (~3), and a series of caudal vertebrae that constitute the tail (*ibid.*).

The shortening of the lumbar region is a particularly salient trait, as it reduces the range of flexion and extension of the lower back, serving to stiffen this region and facilitate orthogrady of the trunk (Shapiro 1993). In the great apes, the ilia (upper pelvic bones) are also high and flare laterally, entrapping the lumbar vertebrae and stiffening the spine further. Hylobatids typically have slightly longer lumbar regions and the ilia are not as flared as in the great apes. Individual lumbar vertebrae are relatively compressed craniocaudally in apes, further shortening this region.

The spinous and transverse processes of each vertebrae serve as attachment points for the muscles of the back. In apes, the lumbar transverse processes emerge from the pedicle rather than from the vertebral body as in monkeys and most other primates (Fig. 3). This more dorsal position of origin serves to move the erector spinae muscles, extensor muscles of the back, further from the intervertebral joints, increasing their leverage and thus the efficiency of the muscles in keeping the torso upright (Shapiro 1993).

The thoracic vertebrae articulate with the ribs dorsally, and the vertebrae are slightly invaginated into the ribcage. In cross section, the ribcage is elliptical in shape, broad mediolaterally but shallow dorsoventrally. This broad chest is significant anatomically as it serves to increase the spacing between the scapula, which are situated on the dorsum (back) of the ribcage rather than the sides, as in most primates. This also has important implications for shoulder mobility (see below).

The lack of a tail in hominoids has been argued to be related to ancestral reliance on cautious arboreal climbing, which makes the tail, as a balancing organ, less necessary (Cartmill and Milton 1977). In hominoids, the tail musculature is reorganized to support the abdominal viscera, a correlate of orthogrady.

**Hominoidea Morphology, Fig. 3** Inferior view of a monkey (*Papio*) (left) and an ape (*Pan*) (right) lumbar vertebra. Note the greater distance between the center of the vertebral body to the transverse process. This greater

distance is thought to improve the mechanical advantage of the erector spinae muscles of the back in keeping the back from bending forward

Although pelvic anatomy is fairly conservative across primates, the great apes have laterally broad iliac blades as noted above. The width and orientation of the iliac blades likely reflects both the broad shape of the thorax and locomotor adaptation. The dorsal surface of the ilium gives rise to the gluteal muscles, which act as extensors of the hip. The relatively large surface area for attachment of the gluteal muscles may be necessary during arboreal behaviors such as vertical climbing, especially at large body sizes.

### Forelimb

The hominoid forelimb is distinctive in being relatively long with highly flexible joints (Young 2003). The shoulder joint is capable of circumduction, or 360° of movement (Larson 1993). As noted above, some of this capacity is afforded by the dorsal position of the scapula, which results in a laterally directed glenoid fossa (shoulder socket). The glenoid fossa is also broad and shallow and gently curved in all directions to serve in this dynamic use of the shoulder (MacLatchy et al. 2000). The overall shape of the hominoid scapula facilitates overhead movement of the forelimb, being relatively short in the

distance from the vertebral border to the glenoid fossa and broad in the distance between the superior and inferior angles compared to other primates (Larson 1993; Fig. 4). This morphology enhances the action of two rotators of the scapula: the serratus anterior muscle, which attaches to the inferior angle, and the trapezius muscle, which attaches to the acromion process and scapular spine (Aiello and Dean 1990; Larson 1993). The acromion process is more laterally projecting and cranially oriented in apes compared to other primates, yielding further mechanical advantage to the deltoid in arm-raising behaviors (Aiello and Dean 1990).

There are several key features of the proximal humerus that distinguish hominoids from other primates. First, the shape of the humeral head is relatively spherical compared to the condition in quadrupedal monkeys, reflecting multiplanar movement of the shoulder (Larson 1993). Second, the deltoid muscle inserts more distally in hominoids, approaching the humeral midshaft. This lengthening of the deltoid increases its moment arm and adds to the lever advantage of the muscle for humeral abduction (i.e., movement away from the midline of the body) (Aiello and Dean 1990;

**Hominoidea Morphology, Fig. 4** Dorsal view of a monkey (*Papio*) (left) and an ape (*Pan*) scapula. In the monkey, the length of the vertebral border (the distance from the superior angle to the inferior angle) is shorter than the length of cranial border (the distance from the glenoid

fossa to the superior angle). In the ape, the vertebral border is much longer than the cranial border. See text for details. Note also that the glenoid fossa is tilted cranially in the ape scapula compared to the monkey scapula

Larson 1993). Third, the projection of the greater tubercle is reduced in hominoids relative to other primates, never extending above the height of the humeral head. This serves to avoid interference with abduction of the forelimb, contributing to the flexibility of this joint (Larson 1993).

Hominoids overlap in much of their forelimb morphology despite their wide ranging and differing locomotor behaviors (Young 2003). However, hylobatids and *Pongo*, who rely more on suspension, have relatively longer forelimbs, more globular humeral heads, further reduced greater tubercles, and more distally inserting deltoids. *Gorilla* and *Pan*, as terrestrial quadrupedal knuckle-walkers, have forelimbs that are closer in length to their hindlimbs, and their humeral heads have relatively less surface area with more robust greater tubercles, fostering more stable glenohumeral joints (ibid.).

The elbow involves the meeting of three bones: the humerus, the ulna, and the radius. The hominoid humeroulnar joint is capable of 180° of flexion and extension. This range is possible because the olecranon process, a proximal extension of the ulna, is greatly reduced in hominoids and so does not interfere with full extension (Aiello and Dean 1990). The elbow is also capable of 180° of supination and pronation, that is, the entire forearm can rotate along its long axis at the humeroradial joint. This is facilitated by a round humeral capitulum (the distal articular surface on which the radial head rotates) and an adjacent, stabilizing buttress (ibid.).

Pronation and supination of the forearm is further enabled by wrist morphology. A fibrocartilaginous disc, or meniscus, intervenes between the reduced styloid process of the ulna and the carpal (wrist) bones. In addition to permitting

greater supination, the meniscus also allows greater adduction at the wrist (deflection toward the fifth digit) than is possible for other primates that have a direct bony articulation between the ulna and the carpals (Aiello and Dean 1990).

The African apes have proportionally larger, broader wrists for compressive weight bearing during knuckle-walking. By contrast, the Asian apes have short and narrow wrists to facilitate greater mobility (Zihlman and Underwood 2019; Fleagle 2013).

Hand morphology similarly varies across hominoids according to their locomotor repertoires, although hominoid hands share in being strong, flexible, and close to equal size with the feet, unlike the hands of monkeys which tend to be smaller than the feet (Zihlman and Underwood 2019). *Pongo* and the hylobatids possess longer, more curved metacarpals and proximal phalanges compared to the knuckle-walking African apes. *Pan* and *Gorilla* additionally exhibit a distinctive dorsal ridge on their distal metacarpals that is correlated with knuckle-walking.

Unlike humans, apes have relatively short, non-opposable thumbs and so must use the side of their index fingers, combined with the thumb, to manipulate objects (Aiello and Dean 1990). The hylobatids are particularly distinct in their thumb morphology, possessing a cleft between metacarpals I and II.

### Hindlimb

The hominoid hindlimb is shorter than the forelimb, except in humans, whose long hindlimbs reflect habitual bipedalism. Hominoid hips are more mobile compared to those of most monkeys, which is important to facilitate climbing and suspensory locomotion (Fleagle 2013). The distribution of the articular surface in the hip socket (acetabulum) is related to movement patterns at the joint. In contrast to the condition in pronograde quadrupedal monkeys, who have a near uniform distribution of articular surface, in hominoids the cranial aspect of the articular surface is expanded, likely reflecting the increased cranial loading of the hip during orthograde.

The spherical femoral head in hominoids has more extensive articular surface than in most other

primates. Apes also tend to have long femoral necks (Fig. 5), elevating the femoral head and increasing mobility. The greater trochanter height in *Pongo* is reduced, facilitating abduction and reflecting the increased variety of hindlimb positions utilized by *Pongo* during arboreal locomotion. African apes have relatively smaller femoral heads and taller greater trochanters compared to *Pongo* and *Homo* (Fig. 5).

The nonhuman hominoid knee is broader than that of monkeys, with a larger medial condyle compared to the lateral condyle (Aiello and Dean 1990). Most explanations for condylar asymmetry invoke enhanced knee rotation and the use of an abducted hindlimb, particularly during climbing (MacLatchy et al. 2000). The femur also has a more bowlegged orientation in some nonhuman apes, such as in *Gorilla*, with more weight being borne on the medial side (ibid.).

The hominoid ankle is more mobile and flexible than that of monkeys. Hominoids have a trapezoidal-shaped distal tibial articular surface, whereas that of monkeys is squarer in shape (DeSilva 2009). This shape may enhance dorsiflexion, the movement that brings the top of the foot close to the tibia, and which occurs during vertical climbing (DeSilva 2009).

The talus is perhaps the best studied of the seven tarsal (ankle) bones. All tarsals have facets that allow each to articulate with one another. In the talus of nonhuman hominoids, these facets tend to be more curved, which allows for increased mobility in the joints. Humans are unique among hominoids, having a shortened talus with facets that have minimal curvature (Parr et al. 2014). This allows for a more stable foot during terrestrial bipedalism (ibid.). The degree of articular facet curvature varies, with *Symphalangus* and *Pongo* having increased curvature, and *Hylobates* and *Homo* having reduced curvature (ibid.). *Gorilla* and *Pan* are intermediate in terms of curvature, reflecting their use of propulsion during quadrupedalism and their need for mobility during arboreal locomotion (ibid.).

The ape foot is capable of substantial inversion, or inward rotation at the ankle, and all apes have long, curved grasping toes with an opposable hallux (big toe). The metatarsals and phalanges of

**Hominoidea Morphology, Fig. 5** Anterior view of hominoid (*Gorilla*, *Pan*, *Pongo*, *Symphalangus*, and *Homo*) and cercopithecoid (*Papio*) femora. Note the roundness of the femoral head in the hominoids. The

height of the greater trochanter is variable. In general, a shorter greater trochanter relative to femoral head height facilitates hip mobility in the hip, particularly abduction and rotation. Scale bars are 10 mm

hylobatids, *Pongo* and *Pan* are relatively longer than those of *Gorilla*. *Pongo* has especially mobile feet, with highly elongated lateral digits and a relatively reduced hallux (Fleagle 2013).

## Soft Tissue Features

### Brain

Although there is considerable overlap between apes and monkeys in the size of the brain relative to body size, the great apes possess the largest brains in absolute size, a parameter that has been closely linked to enhanced cognitive abilities (Deaner et al. 2007). Apart from size, great apes also share several critical neuroanatomical features tied to their complex behavior and sociality, with humans representing the extreme in all

features. For example, great apes possess an expanded prefrontal cortex, a region of the brain associated with working memory and executive function, or goal-directed behavior (Smaers et al. 2017). Hominoids have also been found to exhibit enlarged cerebella relative to the size of the neocortex, although this pattern is only slight in the lesser apes. As the cerebellum is associated with voluntary sensory-motor control, this augmentation serves in fine coordination of motor movements and has been linked to technical intelligence (Barton and Venditti 2014). Great apes also exhibit an expanded anterior cingulate cortex (ACC), a region of the neocortex associated with the interface between emotion and cognition (Allman et al. 2001). This area is involved in social cognition and attention control, allowing for the shifting of focus when confronted with

novel or unexpected information. Within the ACC, the great apes also possess specialized spindle-shaped neurons that facilitate the integration of the prefrontal cortex with other regions of the brain, such as the amygdala. This increased interconnectivity allows for more complex problem-solving and more profound processing of emotional and social information. The largest concentration of these neurons is found in humans, with a decreasing concentration in apes with increasing phylogenetic distance from humans (*ibid.*).

### Gut

Despite some variation in diet, mostly in proportions of fruit versus leaves, hominoid gastrointestinal tracts are similar in overall structure, with a single-chambered, smooth-walled stomach, a small intestine, a cecum terminating in a vermiform appendix, and a large, sacculated colon (Chivers and Hladik 1980).

### Reproductive Anatomy: Relative Testes Size, Sexual Swellings, and Secondary Sex Characteristics

As in other mammals, there is a correlation between relative testicular size and sperm competition among hominoids. Larger testes produce more sperm, so for taxa in which females mate with multiple males during a reproductive cycle, larger testes are favored. Among hominoids, relative testes size and sperm competition are low in both gorillas and gibbons. Paternity data have corroborated these patterns: for pairbonding hylobatids, the male in the pairbond is usually the father; and for gorillas, although they may live in either multimale/multifemale or single male/multifemale groups, the dominant male tends to be the father (Baker and Shackelford 2017). For *Pongo*, where both males and females are solitary compared to other hominoids, the dominant male in a territory has a modest advantage over other males and has somewhat larger testes, higher sperm competition, and lower conception success than in *Gorilla* or hylobatids (*ibid.*).

Both species of *Pan*, the chimpanzee and the bonobo, live in multimale/multifemale groups, where sperm competition is intense, hence relative testes size is the largest among the hominoids. *Pan* is also notable because females have conspicuous sexual swellings in which the genital and perineal skin experience pronounced edema over the course of the menstrual cycle, with maximal tumescence during periovulation. The swelling occurs in some Old World Monkeys, and in most cases, such primates also live in multimale/multifemale societies.

Other notable morphological features associated with sex include the silver hair that marks the back of a dominant male gorilla and the facial flanges that develop in a dominant male *Pongo*. Male *Pongo* also develop laryngeal pouches, allowing them to produce a characteristic “long call.”

### Hair and Sweat Glands

There is a negative correlation between body size and hair follicle density in primates, resulting in large-bodied hominoids having less hair than smaller bodied hominoids (Sandel 2013). Both *Pan* and *Homo* have the same number of hair follicles as other apes of their size but have more vellus (small, unpigmented) hair follicles (Sandel 2013). Nonhuman hominoids have increased eccrine (sweat) gland density relative to Old World Monkeys, and *Homo* has increased eccrine density compared to other apes (Kamberov et al. 2018). Increased sweating and hair loss are both associated with thermoregulatory stress, but more work is necessary to assess distribution and density of eccrine glands across primates.

### Implications of Morphology for Behavior and Evolution

#### Hominoid Morphology and the Terminal Branch Forest Frugivory Hypothesis

As noted, living hominoids are distinguished from almost all other primates by postcranial features related to orthograde and differential use of the fore and hindlimbs such as during suspension or during acrobatic climbing with abducted limbs. The central tenet of hypotheses advanced to

explain the adaptive significance of the acquisition of these positional behavioral adaptations is that they contribute to foraging fitness, by enabling medium- and large-bodied primates to access high quality items like fruit in areas such as terminal branches or the upper canopy where flexible, small supports abound (e.g., Avis 1962; Cartmill and Milton 1977; Temerin and Cant 1983). Suspension may also increase speed and decrease the path length of arboreal travel in these habitats (Temerin and Cant 1983), as well as allow an increase in body size. Suspension has been emphasized in most scenarios of hominoid evolution, but quadrumanous climbing has also been highlighted, as have vertical climbing and orthograde (Fig. 1).

A synthesis by Hunt (2016) of paleontological and neontological lines of evidence led him to suggest that apes evolved their postcranial specializations to feed in the terminal branches on ripe fruit, through coevolution with cercopithecoids whose dental (e.g., bilophodonty) and digestive (e.g., tolerance for tannins, alkaloids, etc.) adaptations, coupled with smaller body size, allowed them to outcompete hominoids for access to unripe fruit, ripe fruit in small patches, and leaves.

A focus on arboreal ripe fruit may have played a role in hominoid cognitive evolution. Arboreal fruit is less abundant and more seasonally variable than both arboreal and terrestrial herbaceous vegetation (leaves, piths, roots, etc.); thus, more frugivorous hominoids are subjected to greater foraging challenges, including greater feeding competition, than are more folivorous hominoids. It has been noted that the large-bodied apes that are more frugivorous, namely chimpanzees and orangutans, show greater use of tools and extractive foraging in the wild than do the more folivorous bonobos and gorillas (Rosati 2017). The more frugivorous great apes also exhibit cognitive predispositions including enhanced spatial memory and greater risk tolerance during foraging (ibid.).

### Hominoid Sexual Dimorphism and Behavior

Sexually dimorphic features in hominoids include body size and musculature, canine size, pelage color and pattern, and a few other anatomical

features (Leutenegger and Kelly 1977). Higher degrees of sexual dimorphism are associated with polygynous mating systems in which males compete for access to multiple females. Increased sexual dimorphism in apes is also associated with their large body sizes and may be related to the long interbirth intervals in apes, which decreases reproductive opportunities for males and therefore increases competition. In contrast, more monogamous species tend to have lower sexual dimorphism as males have higher paternal certainty, incentivizing energy investment in offspring rather than mate competition (Leutenegger and Kelly 1977).

*Gorilla* is highly sexually dimorphic, with an average adult body mass of 162.5 kg for males and 97.5 kg for females in mountain gorillas and 175.2 kg for males and 71.0 kg for females in lowland gorillas (Smith and Jungers 1997; Plavcan and van Schaik 1997) (Fig. 6). Male gorillas possess numerous cranial features that distinguish them from females, including a sagittal crest along the midline of the neurocranium where the temporal bones meet (Fig. 2). Males also possess an enhanced nuchal crest for attachment of the neck muscles that support the head. Male gorillas exhibit deeper upper and lower jaws, necessitated by the significantly larger canines in males compared to females. The male to female canine length ratio is 1.73 (Plavcan and van Schaik 1997).

*Pongo* is also highly sexually dimorphic; males have an average adult body mass of 86.3 kg while it is 38.7 kg for females (Plavcan and van Schaik 1997). Due to the extremely long interbirth intervals (>7 years), reproductively receptive females are rare and thus highly competed for (Leutenegger and Kelly 1977). Adult male orangutans possess several features that are distinct from females, including more well-developed cranial crests, cheek flanges and laryngeal pouches, and considerably larger canines, with a male to female canine length ratio of 1.69 (Plavcan and van Schaik 1997).

Both species of *Pan* (*P. troglodytes* and *P. paniscus*) live in multimale-multifemale mating systems and show moderate levels of sexual dimorphism, with bonobos slightly less

H

dimorphic than chimpanzees. In chimpanzees, average adult body mass is 39.6 kg for males and 29.8 kg for females; in bonobos, body mass is 39.8 kg for males and 32.9 kg for females (Plavcan and van Schaik 1997). The canine length ratio is 1.42 for *P. troglodytes* and 1.38 for *P. paniscus* (Plavcan and van Schaik 1997).

Hylobatids are monogamous in their mating system and show a low degree of sexual dimorphism with body size ratios ranging from 0.9 to 1.1 and canine length ratios ranging from 1.03 to 1.18 across the Hylobatidae family (Plavcan and van Schaik 1997). Some species display pelage dichromatism between the sexes (Fig. 6).

### Hominoid Brain Size, Body Size, and Life History

As noted, hominoids have absolutely large brains. The large brain and associated factors including the cognitive demands of foraging and sociality, as well as the reduced predation associated with possessing both large body size and being arboreal, have all been implicated in contributing to the hominoid life history slow-down. This slow-down is associated with a suite of distinctive features, including single births, long interbirth intervals, a long period of maternal dependence, delayed sexual maturation, and a long life.

While size and evolutionary history are important contributors to the slower life history of hominoids, diet may contribute as well. “The Ecological Risk Aversion” (ERA) hypothesis (Janson and van Schaik 1993) attempts to explain variation that occurs in life history among the hominoids. According to the ERA hypothesis, slow growth in juvenile-aged primates is a response to ecological risks, including predation and starvation. Those who have a lower risk of starvation, or are more folivorous (i.e., because leaves are relatively plentiful), will grow more quickly than those that have a higher risk of starvation, or are more frugivorous (i.e., because fruit is less plentiful). Hominoids generally follow this pattern. For example, folivorous gorillas exhibit *faster* growth rates, given their body size, relative to more frugivorous chimpanzees and orangutans.

### Parallel Evolution and Hominoid Morphology

An enduring question about hominoid morphological evolution concerns which aspects of the postcranial similarities found in all living apes (and that underlie an arboreal niche that involves torso-orthograde suspension and climbing) are due to shared ancestry (homology) versus parallel evolution (homoplasy). Despite a rich fossil record in the Miocene, and dozens of recognized fossil hominoid species, no fossil taxon is unambiguously linked to an extant ape lineage. So, it is not possible to reconstruct the evolution of individual ape genera, in contrast to the human lineage, which has a rich fossil record starting ~4 million years ago. Moreover, there is no simple story of primitive apes gradually evolving into more derived forms.

Some lineages show derived features very early in the evolutionary history of apes, while primitive features persist in younger taxa. For example, one of the oldest stem apes, *Morotopithecus* (known from Uganda and dated at >21 Ma), possessed a stiff lumbar column (MacLatchy et al. 2015), while younger taxa, such as *Sivapithecus*, a genus from Pakistan linked by some to *Pongo* (and dated to ~12.7–8.5 Ma), is reconstructed to have had a more monkey-like, rather than an ape-like, torso (Morgan et al. 2015).

Inferred primitive, monkey-like features of fossils from the upper limb of a possible early human ancestor, *Ardipithecus*, have been used to argue that it, and all other extant hominoid lineages, independently evolved their distinctive broad torso, stiff lower back, and dorsal placement of the scapula (Lovejoy et al. 2009). This line of interpretation reasons that if a recent (~4.4 Ma) taxon like *Ardipithecus* evolved from a lineage with a monkey-like body plan, then all ape lineages, which branched phylogenetically prior to humans, would have had to independently undergo a similar process. Such a scenario raises many questions. If invagination of the vertebral column, widening of the torso, and a dorsal shift in the placement of the scapula evolved multiple times, then what were the selection pressures? Could enhanced arm circumduction alone, in the absence of orthograde arboreality, as some have suggested (White et al. 2015), be sufficient? Or, are shoulder mobility, orthograde, and lumbar stiffness, which seem crucial in order to use fore and hindlimbs differentially and are found in all extant hominoids, critically and functionally linked to arboreality? Furthermore, if all orthograde/suspensory adaptations evolved in parallel, why are modern hominoids so similar for multiple anatomical suites of characters, yet so variable in positional behavior (Young 2003)?

An interesting interpretation of hominoid similarity proposes that developmental constraints may be relaxed in taxa such as apes that have undergone selection for the limbs to be used differentially, as in suspension (Young et al. 2010). Hominoid postcranial evolvability may thus result from selection pressures that decreased fore- and hindlimb genetic integration and allowed the

limbs to evolve more freely (ibid.). Inferred differential limb use in *Morotopithecus* and younger Miocene taxa (MacLatchy et al. 2015) provisionally supports Young et al.'s (2010) supposition that limb “evolvability” may at least be a widespread, if not an ancestral hominoid trait. This emphasis on development mechanisms, rather than the sequence and frequency of postcranial adaptive evolutionary events, is compelling and is having a profound effect on the study of hominoid morphology.

## Definition

Navigation, Cognition, Complex cognition, Conditional cognition.

## Introduction

In the wild, animals need to travel to find their food, sleeping places, and other resources within their home range. Food is naturally dispersed in the environment and comes very often in clumped patches requiring from the animals to move between patches if they want to obtain enough food to survive and reproduce. In addition, fruit availability in the environment is seasonal and ephemeral requiring some additional knowledge to find them efficiently at the right moment. Depending on the environment, the density of food sources can vary dramatically with some food sources being very abundant and others much rarer. The rarer they are, the more important it is to find them in time when facing food competitors. Thus, some navigation skills will be a selective advantage to the individuals.

Navigation has been studied in the laboratory, where by definition the environment complexity is very low and the distances to reach the goal for the subject are extremely small compared to the natural situations. Therefore, early on, experiments were proposed to wild animals in nature to understand the decision process of primates as they look for food. If such experiments were an important improvement over lab studies in terms of ecological validity, they represented still a simplified version of the challenges that primates have to resolve to obtain a balanced diet. Luckily, thanks to constant progress in the statistical analyzing tools, recently it has become possible to study the navigation of individuals when looking for food in the highly complex tropical rainforest situation. This has allowed to understand unexpected and complex cognitive skills in wild primate navigation skills.

## About Navigation

Depending on the diet specialization of the species, the challenge to find patchy food sources may require sophisticated navigation skills. Folivores, for example, will be able to find food more easily, as leaves are overabundant and constantly present in the tropical forests. Obviously,

folivores are also selective, in the sense that they do not eat leaves indistinctively, but select leaves from some species only, and often as well prefer young leaves over older ones (Clutton-Brock, 1975; Struhsaker, 1975). A large number of primate species are omnivores, eating vegetable and animal food types with relatively few examples of dietary specialization, like some small nocturnal species, such as galago, dwarf lemur, aye-aye and the loris that are substantially insectivorous, or some marmoset species that specialized in eating gums (Garber, 1987). Insectivores face a rather similar situation, as insects are quite abundant in the forest, but require from the hunter swift reactions, as insects will avoid being captured. Therefore, insectivores tend to be small-bodied primates (Garber, 1987). Generally, primates eat at least some species of fruits, and great apes, except for the gorillas, eat mainly fruits and preferably ripe fruits. Frugivorous, on the other side, have to navigate more precisely, as large fruiting trees that can abundantly provide food to a group of individuals are rare and often dispersed throughout the forest. Since fruits are ephemeral and seasonal, we should expect different selective pressures on the cognition of the individuals depending on their diet to forage efficiently in the habitat.

Fruit-eaters face the challenge not only to find the specific trees, but find them timely when they are ripe. Even an unspecialized fruit eater, like the baboon, will eat them only once they start being consumable, while the chimpanzees will wait until they are fully ripe and tasty. This means that not all fruit-bearing trees are a food source, and when they become edible will be species-specific. In all cases, fruits are very seasonal and can be eaten only over a limited period of time, requiring flexibility from the primates looking for different fruiting tree species at different times of the year. At this point, tree species distribution, abundance, and fruit production become essential factors for detection by the fruit eaters, and the rarer and more widely dispersed fruiting trees are, the more demanding it will be to find them. In other words, navigation complexity to find food will be a function of diet as well as of distribution of available food sources.

### Navigation in the Laboratory

Research on navigation have often been done in the laboratory where for reasons of better control of the different possible confounding variables, the ecological contexts presented are abnormally simple preventing a deeper understanding of the cognition needed in nature. In the sense that the spatial challenges that can be studied in such a simple space will limit the expression of a more complex cognitive performance. For example, many studies of navigation require the subject to find its way in two-dimensional maze, constituted of two to three lateral branches (like the Morris Water Maze, Tan et al., 2017), or alternatively to place objects in a simple model with other objects rotated in different ways (like the Three Mountains Test, Newcombe, 2019). Rarely do the subjects have to actively move to perform the test, and when needed, it will be over very short distances.

Such well-controlled laboratory experiments, exploring animal spatial cognition, address often questions that have very little ecological validity, as they differ significantly from the challenges encountered in nature, and as such it is very difficult to see how they can contribute to an understanding of natural navigation skills in primates. Discrepancies in results from captive studies with such ones done on wild living animals have often puzzled scholars, as they are very hard to understand and put in perspectives. On one side, captive animals may appear to outperform wild counterparts. Janson and Byrne 2007 discussing on Cramer and Gallistel's (1997) results about captive vervet monkeys appearing to use for the first time a "traveling salesman"-type of foraging said: *"The difference between results could be due to several factors: (1) the species may differ intrinsically in cognitive use of spatial knowledge, (2) the wild monkeys have to deal with much larger spaces across which they cannot see their foraging goals and thus cannot precisely estimate the distances to each goal, let alone the distances between them, (3) the wild monkeys are hungrier and discount more distant resources so heavily that they do not include them in their decisions, (4) the wild monkeys may benefit from foraging in*

*nearby areas they already know to be free from competitors—and the list could go on. Although both results are intriguing, the captive result may tell us little about how a cognitive potential is used in the wild"* (Janson & Byrne, 2007, pp. 358–359).

On the other side, captive animal studies may underestimate the abilities of wild counterparts to navigate. For instance, work on captive capuchin monkeys that needed to find food in boxes rotated when they could not see the rotation suggests that they learn only simple associations between a goal and a local landmark (Poti 2000). Nevertheless, wild capuchin groups appear to use information about the location of at least two resources relative to each other to decide on a foraging route. Janson and Byrne (2007) concluded: *"Thus, their apparent limitations in captive tests either do not apply to the wild or they use some other mechanism to circumvent this cognitive limitation. This caution applies particularly in the case of captive-reared primates, which may not have had the experience to develop or practice navigation abilities in large-scale space* (Menzel & Beck, 2000)" (p. 359).

Similarly, spatial skills in chimpanzees have been studied extensively in the laboratory by proposing an environment drastically less challenging than the wild one, with the aim to understand their ability to conserve length and distance, to rotate objects in landscape, or to plan in the future and remember object locations (e.g., Beran & Minahan, 2000; Rooijakkers et al., 2009; Poti, 2000; Poti & Langer, 2001; Premack, 2007; Premack & Premack, 1983). Such experiments generally required from the captive chimpanzees sitting to follow invisible displacements of grapes or sweets hidden under cups that are moved or not, pile wooden blocks on one another, or place miniature houses or cars in landscape oriented differently in space. The scientists tend to agree in finding limitations in chimpanzees both in the vertical and horizontal displacements. This could have been expected, considering that the bare environment experienced by captive chimpanzees for years do not select for much spatial skills when looking for food or a sleeping place.

### Navigation in the Natural World

Contrary to individual animals kept in captivity, finding food requires from the wild individuals an important time investment to forage over extended spatial areas where the distances covered prevent a direct visible comparison of the different food sources. Just to take a few example, white-faced capuchin (*Cebus capucinus*) adults devote between 50% and 65% of the day to foraging and traveling and cover a day range of approximately 3000 m (Garber & Brown, 2005). Wedge-capped capuchins (*Cebus olivaceus*) spend almost 70% of their active hours searching and processing food, while traveling 2141 m per day. Spider monkeys (*Ateles spp.*) forage in small fission-fusion parties within a home range of many hundreds of hectares and travel up to 3000–5000 m per day. Mantled howler monkeys (*Alouatta palliata*) travel in a line within a home range of 2–40 ha, with a day range of 100–450 m (Garber & Jelinek, 2005). Chimpanzees in the Tai forest range within a territory of 10–40 km<sup>2</sup>, looking for food for about 40% of the day time, with a day journey length of 5000–10,000 m (Boesch & Boesch-Achermann, 2000).

### Monkey Navigation with Field Experiments

Therefore, studying the cognition of navigation is equally challenging to the researchers, as we need to know the availability of food and the location of the trees with fruits at the time the individual is looking for food. As this needs to be known for ephemeral and seasonal food sources, this requires an unusual investment. To circumvent such challenges, some researchers skillfully developed an experimental paradigm whereby they presented food on a small number of platforms (Janson, 1998; Janson & Byrne, 2007; Garber, 1988; Garber & Jelinek, 2005). Such experiments allowed the researchers to know constantly the position and the amount of food available to the monkeys. However, they could not control for the other food types that might have been available at the same time in the forest, which could have interfered with the foraging route adopted by the monkeys. Inasmuch as possible, some studies tried to present the

experiments during periods of the year when food availability was very low, and the individuals were seen to almost exclusively feed on the food provided by the researchers.

In monkeys, the studies concur to show the importance of landmarks and memory that seem the main elements for the individuals or groups to find the food sources and be able to revisit them by applying an energy-optimizing strategy. In addition, they confirmed some of the negative effects of captivity on the development of cognitive capacities when it comes to find food (Janson & Byrne, 2007). In addition, since food is naturally only temporally available for a short period of time, capuchin monkeys were found to possess and use integrated memories of prior food-patch use, including those where the patch is relative to their current location, productivity of the patch, and how long it has been since they last visited the patch (Janson, 2016).

Orientation in the tropical rainforest remains a constant challenge to find food sources that are seasonal and often hardly predictable. The tropical rainforest is constituted by an impressive richness of a multitude of tree species, ranging from the smallest ones to the tree giants emerging at some 50 m of height. As the tropical rainforest is home of the largest biodiversity of primates, this is a challenge that most of them have to resolve. Whenever a monkey or an ape moves in the forest searching for food in the trees or on the ground, the very limited visibility within the forest makes finding ripe food quite challenging.

### Chimpanzee Navigation in the Tropical Rainforest

If the challenges of finding food in chimpanzees sounds at a first look very similar to what monkeys face, the challenges are exacerbated: Chimpanzees' home range is much larger than the monkey ones, being between 10 and 40 km<sup>2</sup> wide. In addition, they are specialized ripe fruits eaters (over 75% of their diet). Finally, they have a very diverse diet eating up to 150 different food items and daily up to 8 different fruit species. These three aspects of the chimpanzee life increase the demands on navigation in the forest.

Therefore, the selection of the fruiting trees carrying ripe fruits will be specially demanding, as the time window when trees are carrying the fruits of the appropriate state of ripeness requires precise temporal memories to find the appropriate trees.

Thus, cognitive complexity should be expected in spatial skills, as the dense African rainforest strongly limits visibility on the ground, which represents a distinct challenge for an animal species ranging daily over 10 km (Janmaat et al., 2013a, 2013b; Normand et al., 2009). The challenge of finding trees full of ripe fruits should not be underestimated, as the likelihood to find a fruiting tree during a walk in straight line has been estimated to be one for every 10–21 km walked (Janmaat et al., 2016; Pontzer & Wrangham, 2004). Knowing that a chimpanzee eats fruits daily from about eight different species of fruits and travels daily a minimum of 2–4 km, the selective pressure to improve spatial skills in the forest is massive. This is further complicated by the fact that fruit production is not only seasonal, but very irregular: trees bear ripe fruits at most for a month, and, within a same species, fruit production can vary extensively among individual trees, across season, and across years (Janmaat et al., 2016). Thus, in wild chimpanzees, detailed spatial knowledge to select and reach trees from all possible directions needs to be combined with long-term memory, botanical knowledge, and long-term planning of movements (see Normand & Boesch, 2009; Normand et al., 2009; Janmaat et al., 2013a, 2013b, 2014, 2016).

Thanks to the progress of statistics, we were not only able to explore the complexity of the spatial knowledge, by including a large number of factors into the model (between 4 and 6), but as well to control for the contextual dimension, by including a number of control variables (up to 7) (Janmaat et al., 2014). It is only with such a complex model that we could identify the level of complexity of the chimpanzees' spatial skills when searching for ripe fruits in such high diversity and low-visibility forest. Detecting such level of cognitive complexity is presently out of reach from captive studies and has only become possible thanks to the recent progresses of our statistical tools. In a review of the challenge to find fruits in the African tropical

forest, the authors concluded: *“In short, ecological intelligence involves much more than solely remembering the spatial location of a number of food trees within a large home range. We conjecture that successful foraging depends on a combination of cognitive skills, especially an ability to obtain, store and retrieve knowledge on temporal availability of food in individual trees. Here, we hypothesized on the existence of a suite of cognitive strategies that chimpanzees can employ to maximize food finding efficiency in periods of scarcity by using individual and species-specific information on the predictability of their food in individual trees”* (Janmaat et al., 2016, p. 15).

Navigation in wild chimpanzees can be further complicated by their ability to not only include a suite of information about the fruit trees but by their ability to include material information about objects. For example, Tai chimpanzees are famous for cracking hard nuts with the help of heavy and hard natural-occurring hammers. These stone hammers can be rare in the forest and some of the tree producing nuts are equally rare: Chimpanzees are therefore required to make long transports of the hammers, if they want to crack the very hard *Panda* nuts (Boesch & Boesch, 1983, 1984; Sirianni et al., 2015). However, to do so, chimpanzees do not only consider the distance of the transport needed to carry the stone hammer from its original location to the nut-producing tree, they also consider the hardness and the weight of the hammer. Indeed, for hard nuts a hard and heavy hammer is mandatory to crack open the nut, and decide where the nuts will be cracked, on the ground or directly on a branch in the tree.

Thus, navigation in the forest for chimpanzees does not only mean having a notion of direction and distance, but also be able to combine these with additional information that allows them to anticipate the location of a food source, its quality, by memorizing its previous production, and its likelihood of the state of production. Such type of navigation in nature is not only about spatial knowledge but it combines in the mental map contextual and past information about the environment that allows to make predictions about the decisions to take, such as to find high-quality food or which type of hammer to select.

## Conclusion

Navigation for forest living primates requires the ability to remember the locations of tree out of sight, to be able to reach them from different directions as they forage in the forest, and to re-orient themselves flexibly with regard to different food sources and different directions. If this needs still to be demonstrated for different primate species, the evidence is already strong for species, like capuchin monkeys and chimpanzees. Such abilities are developing progressively in humans between the ages of 6 and 12 years with important individual differences (Newcombe, 2019). As in humans, primates with harder challenges develop more elaborate navigation abilities.

A decisive complexity in navigation is seen in chimpanzees, as spatial information is combined with many contextual information making the decision process conditional on different factors. These observations stress the need to consider the interactions of the individuals with its environment and within their specific population biology of the population. Navigation in nature is survival important, and therefore, we should expect very high selection pressure to resolve the ecological challenges efficiently.

## Hominoidea Sensory Systems

Amanda D. Melin

Department of Anthropology and Archaeology,  
University of Calgary, Calgary, AB, Canada

## Synonyms

Apes; Eyesight; Gustation; Haptic sense; Humans; Olfaction; Sensation; Smell; Taste; Touch; Vision

## Definition

Apes and humans comprise the superfamily Hominoidea. Together with their sister superfamily, the monkeys of Africa and Asia (Cercopithecoidea), they form the parvorder Catarrhini. While humans are now exceptionally widespread, other members of the Hominoidea are restricted to a few tropical regions of Africa and Southeast Asia, and are among some of the most imperilled primates globally. Sensory systems form the interface between animals and the external world and are also used to sense and respond to their internal environment. In performing these roles, sensory systems play a key role in shaping the behavior, ecology, and morphology of species, as well as their molecular underpinnings. Like other primates, humans and apes use their sense of touch, smell, vision, taste, and hearing to find and select foods, avoid predators, and communicate with members of their own and other species. In this section, the sensory systems of hominoids are discussed, with a focus on similarities to and differences from other primates.

## Introduction

Five systems are traditionally discussed in the context of primate sensory ecology (reviewed in Kawamura and Melin 2017): vision, olfaction, hearing, touch, and taste. I cover each of these here, beginning with those used in perception over long distances (hearing, olfaction, vision), and ending with senses engaged at close proximity (taste and touch). It is important to note, however, that hearing, olfaction, and vision often also play important roles in close-distance evaluation (Melin and Veilleux in press). While research on primate sensory systems has historically been heavily biased toward the visual system, more attention has recently been given to olfaction, taste, and audition, with the sense of touch still relatively understudied (Dominy et al. 2001; Heymann 2006; Melin and Veilleux in press). For each sense, the main morphology, genetic underpinnings, and behavioral uses are summarized, with a focus on similarities and differences

with other primates and mammals. It is also worthwhile to mention that hominoids also possess other sensors, such as thermal sensors and proprioceptors, that are used to monitor both the internal and external environment. These senses play essential survival roles but are not considered further here.

## Audition

Hearing is a mechanical sense and often the farthest-reaching sense due to propagation and perpetuation of sound waves over long distances but is also involved in the perception of quiet sounds heard over short distances (Dominy et al. 2001). Unlike other primates, including the tarsier and strepsirrhines, hominoids – along with other anthropoid primates – have lost highly mobile ears, and their pinnae (external ear morphology) are relatively small (Coleman and Ross 2004). Approximately 70 genes have been linked to the auditory sense in humans (Frenzel et al. 2012), but a comparative study of the genetic basis and evolution of this sense across Hominoidea is almost nonexistent. Despite the reductions in morphology and concomitant changes in sensory abilities relative to other mammals, including tarsiers, lemurs, and lorises, the sense of hearing remains critical to humans and apes, and much research has investigated audition in the context of social communication (e.g., Hashiya and Kojima 2008).

Audition plays an essential role in hominoid communication as it allows the vocal cues and signals produced by conspecifics and heterospecifics to be heard and evoke behavioral responses. For example, pant hoots produced by chimpanzees vary among social contexts and receivers may respond in context-specific ways (Clark and Wrangham 1993). The spectral frequencies to which hominoid auditory systems are tuned are shaped by natural selection and by physiological and phylogenetic constraints. Species-specific audiograms – which present the audible thresholds for different frequencies – have been generated for several species (e.g., Heffner 2004). Comparative behavioral, anatomical, and computational studies have related aspects of the audiogram to the size and shape of

the inner ear bones (auditory ossicles) that transmit sound waves to the eardrum through vibrations generated in the external world, which are eventually sensed as audible noise. These studies have enabled fascinating research into the sensory ability of extinct hominoids, such as *Paranthropus robustus*, whose auditory ossicles in part resemble *Homo* and in part resemble those found in African and Asian Great Apes (Quam et al. 2013).

In foraging contexts, the sense of hearing can be used to locate food sources. For example, fruiting trees are identified by the food-associated vocalizations of conspecifics or other foragers or by the sounds of dropping fruit (Dominy et al. 2001). Some hominoids, including chimpanzees and humans, also tap fruits, and hollow sounds may be used as a sign of ripeness (Melin and Veilleux *in press*). Hunting for vertebrate as well as invertebrate prey also can involve active acoustic foraging (tap scanning), as exemplified by the specialist aye-ayes (Ramsier and Dominy 2012), or passive listening. For example, chimpanzees have been noted to change activities to hunting in response to prey-derived sounds (Boesch and Boesch 1989). In addition to being hunters, apes and humans can also be prey, and auditory detection of both alarm calls from other animals as well as detection of predator-generated noises may have shaped hominoid sensory ecology and evolution in complex ways. Finally, hearing often works in conjunction with other senses. For example, primates will automatically turn their heads to fixate their gaze upon hearing a sound of interest, known as the “visual orienting reflex.” Intentional multisensory investigations of stimuli are also common during foraging (Melin and Veilleux *in press*), and multiple senses are also simultaneously involved during communication. Visual cues such as lip movements appear to reinforce and improve (or confuse or interfere with, if mismatches are presented) auditory communication in humans and other primates (Sugihara et al. 2006).

## Olfaction

The sense of smell is a versatile and complicated chemosense. The nasal epithelium houses

olfactory receptors that can bind with multiple volatile compounds. Uptake of odors can take place long distances from their source; however, the sense of smell also plays an important role in assessment at very close distances, such as during active sniffing of a food item or a conspecific (Melin and Veilleux [in press](#)). Scents can persist in the environment for long periods, such that the sense of olfaction can be informative about past events, such as another group of animals being present in a location through scent marks. Evidence that primates make use of odors from conspecifics can be found in behavioral studies. For example, chimpanzees actively investigate urine odors, especially urine from nongroup members (Henkel and Setchell [2018](#)).

Odorants of biological relevance to apes, humans, and other primates potentially include predator-related odors, scents from foods that can either stimulate ingestive behaviors or cause rejection of foods, and body odors of conspecifics that can seemingly lead to attraction or detraction (Shepherd [2004](#); Dominy et al. [2016](#)). However, olfaction remains a poorly understood sense, and the types of odors that primates, including hominoids, can detect (along with their sensitivity thresholds and functional roles) are poorly resolved.

A common dialogue in the story of primate evolution is that the sense of smell became increasingly unimportant and markedly lower in the ancestors of hominoids. However, this view is slowly and consistently dissipating, and it is now acknowledged that primates are more sensitive to some odors – such as those common in ripening fruits – than are other mammals renowned for their sense of smell, including dogs (Laska et al. [2000](#)). Furthermore, while it was previously believed that apes have fewer functional genes responsible for coding olfactory receptors (OR) than monkeys have, this incorrect idea has been recently overturned, although the loss of OR genes may be more common in species with folivorous diets (Niimura et al. [2018](#)). Humans and apes seem to have several hundred, perhaps as many as 400, functional olfactory receptor genes. While more seemingly functional OR

genes have been reported for the wet-nosed (strepsirrhine) primates, especially the nocturnal species such as mouse lemurs, the number for hominoids is similar to those reported for other haplorrhine primates (Niimura et al. [2018](#)). A consistent trend in primate evolution is for highly species-specific loss and gain of OR genes, and extensive heterozygosity in OR genes, leading to individualized sensory experiences (Hoover [2010](#)). Anosmic humans report difficulties with both social and food-related behaviors, and as methodologies advance, future research will continue to reveal the breadth and depth of roles our sense of smell plays (Hoover [2010](#)).

## Vision

Vision, the perception of electromagnetic energy as visible light, is a key sense to humans and apes. Like other primarily diurnal anthropoids, hominoids have forward-facing eyes and acute spatial vision due to high densities of cone photoreceptors in the retina. Unlike many mammals, hominoids and other primates have round pupils and relatively large eyes (Banks et al [2015](#)). Vision is involved in many aspects of daily life, including finding and selecting both conspicuously colored and cryptic foods and predators, as well as communicating over short-to-mid distances with conspecifics. While their visual acuity and color vision fall short of the abilities of some birds, hominoid primates are outstanding among mammals in their capacity to resolve fine detail and to see a wide gamut of colorful hues (Kremers [2005](#)).

All species of apes, including humans, have routine trichromatic color vision, meaning all individuals have three types of cone cells: short wavelength (blue) sensitive, middle wavelength (green) sensitive, and long wavelength (red) sensitive. This system of color vision allows individuals to distinguish greenish from reddish hues, as well as bluish from yellowish hues (Kawamura and Melin [2017](#)). Hominoids share this uniform trichromacy with other catarrhine primates

(African and Asian monkeys), but the color vision of platyrrhines and strepsirrhines is more variable and is typically either characterized by uniform or sex-linked dichromacy (red-green colorblindness; Kawamura and Melin 2017).

The roles of color vision have been explored at some length in humans and among some monkeys and lemurs. While some of the benefits of trichromacy for food detection and selection, likely extend to members of the hominoidea, little has been asked about the role of color in intraspecific communication outside of humans (reviewed in Moreira et al. 2019). Human color vision is surprisingly different from apes and other catarrhine primates. Available studies suggest that humans have a far greater number of opsin gene mutations than other hominoids, and as a result, a much higher number of individuals with color vision anomalies (Kawamura and Melin 2017). Whether this reflects relaxed selective pressures or potentially selection favoring low frequencies of dichromatic and anomalous trichromatic phenotypes in populations remains debated, as dichromacy may confer adaptive benefits for breaking camouflage.

## Taste

Like olfaction, gustation – our sense of taste – is chemosensory and works closely with our sense of smell to perceive chemicals in the environment. Taste receptors are expressed on the surface of the tongue, and ligand binding stimulates downstream responses. Perception of tastants can stimulate acceptance/preference behaviors or rejection/avoidance behaviors. For example, chimpanzees and humans show behavioral preferences for solutions containing sucrose over those comprised of water, and frugivorous hominoids and other primates can detect sugar in low concentrations, an adaptation for the frugivorous components of hominoid diets (Remis 2006). The bitter taste receptors, on the other hand, are more diverse and are involved in the avoidance of bitter – and potentially toxic – compounds (Wooding et al. 2006).

The genetic basis of taste perception in hominoids is simpler than that of olfaction and, in part as a consequence, is better understood. Humans possess around 25 taste receptor genes coding for bitter sensors and 3 genes coding for taste receptors that are responsible for sweet and umami sensations. Evolutionary diversification coinciding with adaptive radiation can be seen in bitter taste receptor (TR) genes of apes and other primates (Fischer et al. 2005; Imai et al. 2012). Available research using comparative genomic approaches, and heterologous cell expression assays that allow TR genes to be expressed and investigated in the lab, have led to numerous advances in our understanding of functional adaptive variation between species. However, these types of studies remain in their infancy, and much work remains to be done.

## Touch

The haptic sense, or sense of touch, is perhaps the least understood of the five senses discussed here. Like audition, it is a mechanical sense, and the stimulation of cutaneous mechanoreceptors, that is, the touch receptors sensitive to vibrations and indentations of the skin (Merkel's disks, Meissner's corpuscles, Ruffini's corpuscles, and Pacinian corpuscles) generate electrical impulses perceived by the brain through the somatosensory system. Touch is used during foraging to assess (e.g., by squeezing) and to manipulate foods prior to and during ingestion, most commonly in the hands, feet, and mouth (Dominy et al. 2016; Melin and Veilleux *in press*). Some apes and humans are also adept at fashioning tools to aid foraging, a task that requires manual dexterity and extensive abilities for fine discriminative touch for detailed manipulation of objects (Russon et al. 2015; Lamon et al. 2018). Given the capacity for fine manual motor control possessed by tool-making hominoids, it is likely their sense of touch is derived relative to other catarrhines and primates, but few comparative studies of the morphology or genetic basis of touch have addressed this interesting question. Turning to the social realm, touch plays a key role

in bonding and wellbeing through direct contact, grooming, and other social activities involving touching (Nummenmaa et al. 2016).

Perhaps unsurprisingly, the mechanosenses – hearing and touch – may share a common genetic underpinning. This hypothesis was brought about by observations that people with hearing impairment can also suffer from poor haptic acuity. Although the molecular basis of touch is still relatively unknown compared to other senses, several candidate genes have recently been identified (Frenzel et al. 2012). Comparative analysis of the haptic sense across primate species with varying manual and buccal morphologies and behaviors would be a fascinating area for future work.

## Conclusion and Future Directions

Sensory systems play crucial roles in hominoid life by facilitating interactions with the physical and social environments. Research on the sensory ecology of apes and humans has shown how sensory systems contribute to adaptation and evolution, but much remains unknown, including large gaps in our understanding of genotype-phenotype interactions of nonvisual senses, use of the chemosenses during social interactions and foraging, and dynamics of multimodal sensory integration across contexts. Future research in these areas will continue to shed light on the adaptive origins of hominoids and other primates.

## Definition

*Homo erectus* (upright man) is an extinct species of human that occupies a fascinating spot within the human evolutionary lineage. These prehistoric hunter-gatherers were highly successful in adapting to extremely different habitats across the Old World, as fossils connected with this species have been found ranging from Africa all the way to Southeast Asia (Brauer et al., 1992). With the earliest remains appearing around 1.9 million years ago (MYA), and continuing into the Middle Pleistocene, *Homo erectus* spanned an extraordinarily large time frame. However, the amount of variation between different fossils from different times and places has raised questions regarding the actual classification of the species, and its accurate role in the evolutionary story.

## Who Were They?

In the 1890s, fossils found at the site of Trinil by Eugene Dubois on Java, Indonesia, became the first to be classified as *Pithecanthropus erectus* (Dubois 1926). After this discovery, more *Homo erectus* fossils were found in Indonesia, then China, and finally in Africa from the 1960s. This species most likely originated in East Africa or perhaps Eurasia from an earlier species of *Homo* (most generally thought to be *Homo habilis*) (Grine et al., 1996). They may have given rise to *Homo heidelbergensis*, which is seen as a direct precursor of *Homo sapiens*.

The difficulty is, however, that the fossils that have been designated as *Homo erectus* span an almost preposterous amount of both time and geographical distance and show huge variations when they are examined together. The question is whether they can really be classified as one species, or whether these fossils comprise a number of related species.

On the one hand, there are those who contend for a broad, single-species model (*Homo erectus sensu lato*), surrounding all or almost all fossils from Southeast Asia to Africa that have been classified so far (Grine et al., 1996). In this vision, the distinction falls within the range of an otherwise cohesive species and might be due to the adventurous, globe-trotting nature of this species, with time and space impacting on their physiques. This broad definition is so convenient, though, that it becomes tempting to toss every new fossil find that seems to somewhat match the characteristics of *erectus* in with this group.

On the other hand, a narrower definition of *Homo erectus* has been recommended that excludes all of the African fossils, or at least the part found at Koobi Fora, suggesting that these constitute a different species, named *Homo ergaster* instead (Klein 1999). *Ergaster* is then seen as the species that is linked with the lineage leading to *Homo sapiens*, whereas *Homo erectus sensu stricto* (in the strict sense, so only the Asian part) may have been a dead end.

This discussion will no doubt continue until more fossils are obtained to address this issue. At the moment, the prevailing view is that the characteristics of the fossils support the single-species hypothesis – so *Homo erectus* in the broad sense is the current preferred nomenclature.

## Geographical Extend

Fossils assigned to the broad definition of *Homo erectus* are found all the way from Africa to Southeast Asia (Johanson et al., 1996). Areas and sites include Trinil on Java, Indonesia, China, Eurasia (including Georgia, where finds at Dmanisi are so puzzling they seem to blur the lines between *Homo habilis*, *Homo rudolfensis*,

and *Homo erectus* and might even end up qualifying as a separate species (*Homo georgicus*)), East Africa (sites at for instance Olduvai Gorge), and South and North Africa. Some finds in Western Europe have also at some points been characterized as *Homo erectus*, but there is now fairly broad agreement that most of these forms are better matches with *Homo heidelbergensis*.

*Homo erectus* was an early species of adventurers, thought to have started their lengthy migration out of Africa, through the Middle East, the Caucasus, and ultimately East Asia around 1.9–1.8 MYA, reaching China and Indonesia by ca. 1.7–ca. 1.6 MYA. But what spurred them on? In 2016 (East Africa) proposed a model suggesting that *Homo erectus* followed the large herbivores during their migrations, while also keeping an eye on flint deposits, and avoiding areas populated by carnivores, at least early on in their association. (We can ignore this as this is not required).

## What Did They Look Like?

*Homo erectus* was both bigger and smarter than previous *Homo* species (Van Arsdale, A. P., 2013). Their skeletons were basically similar to modern humans although they were heavier). They were the first humans to have limb and torso proportions similar to modern humans, which allowed them to walk upright on 2 ft and literally travel the world.

A few of these humans were relatively tall, with the African-based segment reaching a standard height of a lofty 170 cm, much like with our present-day population. *Homo erectus* across dissimilar regions demonstrates a wide variety of sizes, ranging between approximately 145 cm and 185 cm in height and weighing between 40 kg and 68 kg. *Homo erectus* was without a doubt a lot taller relative to previous human species.

Similarly, compared to *Homo habilis*, *Homo erectus* not only was significantly bigger but it also grew larger across evolutionary time. Early members of this species have cranial capacities between 600 cm<sup>3</sup> and 800 cm<sup>3</sup>, but later *Homo erectus* go beyond 1000 cm<sup>3</sup>, which falls within the range seen in *Homo sapiens*. They had heavy

brow ridges and a low cranial vault, and their teeth were smaller (*Homo erectus* 2018) and more slender than those of earlier humans.

## Mode of Life

*Homo erectus* relatively large brains and bodies required a lot of energy to sustain them. They ate a diverse and broad diet, perhaps including tubers, and definitely a substantial amount of meat (Groeneveld 2017). Animal leftovers with well-defined marks left by butchery have been found near *Homo erectus* skeletons, which suggests that they frequently utilized animal carcasses – most likely through both hunting and scavenging – at least 1.75 MYA (Groeneveld 2017).

There is evidence that *Homo erectus* knew and used fire. The earliest proof for the use of hominin fire dates back to around 1.8 MYA (Brown et al., 1985), and from at least 500,000 years ago, cooking became widespread. From 400,000 years ago, well within *Homo erectus*' time span, human species were noticeably and purposefully using fire. Hearths lit up the living spaces of these societies and provided not just a means for cooking food but also provided heat, protection from predators, and were good hubs for social communication, often in caves or overhanging cliffs.

*Homo erectus* was also a toolmaker, related to the Oldowan, but more generally with Acheulean stone tool manufacturing, and was often linked with the formation of the first hand-axes, which represent the first major modernization in stone tool technology. A broader set of tools would have helped *Homo erectus* stay alive across a broad range of environments, which may explain the wide geographic range in which *Homo erectus* fossils have been found.

When it comes to picturing *Homo erectus* around a hearth inside a cave, feasting on a butchered bison steak, we cannot tell whether they would have had proper conversations or not. Several social elements must have been present, but verbal communication is a tough one to determine. Anatomical clues cannot confirm or deny the capability for verbal communication or a small kind of human-like proto-language in

*Homo erectus*, and since no DNA exists, scientists cannot look for the FOXP2 gene, which is connected with verbal communication in humans and is seen in both the later Neanderthals and Denisovans (Groeneveld 2017).

On the whole, *Homo erectus* may well have been the most primitive species within this lineage to show so many human-like characteristics.

## Other Remarkable Fossils

The first *H. erectus* fossil found was a one-million-year-old skull discovered by Dutch surgeon Eugene Dubois in Indonesia in 1891. Other remarkable fossils include the 1.77-million-year-old skull of an aged man, exposed in Dmanisi, Georgia (Lordkipanidze et al., 2013). According to the Smithsonian Institution, the man had missing most of his teeth long before he passed away, causing much of his jaw to degrade (Smithsonian). This leads researchers to consider that other members of the man's social group must have cared for him, one of the first examples of such sympathetic social performance in a human ancestor.

## Relationship to *Homo sapiens*

### The Question of Origin

A small number of researchers have opposed the view that *H. erectus* was the direct ancestor of later species, including *Homo sapiens* (Jelinek 1978). Louis Leakey (1960) argued that *H. erectus* populations, particularly in Africa, overlapped in time with *Homo sapiens* and therefore could not be ancestral. Some support for Leakey's point of view has come from analysis of anatomic characteristics exhibited by the fossils. By emphasizing a difference between "primitive" and "derived" character in the renovation of associations between species, some paleontologists have attempted to demonstrate that *H. erectus* does not make an appropriate morphological ancestor for *Homo sapiens*. Because the braincase is long, low, and thick-walled and presents a strong brow ridge, they claim that

*H. erectus* shows derived (or specialized) features not shared with more modern humans. At the same time, *Homo sapiens* does share several characteristics, including a rounded cranium, with earlier hominins such as *H. habilis*. For these reasons, a number of paleontologists (including Leakey) think that the more slender, or “gracile,” *H. habilis* and *H. rudolfensis* are more closely related to *Homo sapiens* than is *H. erectus*. These findings are not broadly accepted, however. Instead, studies of size in human progress point out those representatives of *Homo* can be grouped into a sensible ancestor-to-descendant sequence showing increases in body size (Franciscus et al., 1988, Tobias and Rightmire 2006). Despite having a heavier, more flattened braincase, *H. erectus* and the African representatives of the species sometimes called *H. ergaster* fit nicely in this sequence.

Even if *Homo erectus* was ancestral to modern humans, there is still uncertainty as to how and where *H. erectus* ultimately gave increase to *Homo sapiens*. In the study of human evolution, this is a most important question. Some hypotheses have been proposed, but there is still no firm consensus supporting models of gradual change as opposed to scenarios of hasty evolution in which change in one state is followed by movement of the new populations into other areas.

### Theories of Gradual Change

A conventional paleontological view is that a species may be transformed gradually into a succeeding species (Tobias and Rightmire 2006). In the evolutionary series, successive species are called chronospecies. Because these changes are small and seen over a long time period, the borders between chronospecies are almost impossible to determine by means of any objective anatomic or functional criteria. Such a chronological boundary may have to be drawn arbitrarily between the last survivors of *H. erectus* and the earliest members of a succeeding species. The problem of defining the end point of chronospecies is not unique to *H. erectus*; it is one of the most vexing questions in paleontology. A steady transformation with stability between successive forms has been postulated especially

for North Africa, where *H. erectus* at Tighenif is seen as ancestral to later populations at Rabat, Temara, Jebel Irhoud, and elsewhere. For Southeast Asia, gradualism has also been hypothesized, where *H. erectus* at Sangiran may have given rise to populations such as those at Ngandong (Solo) and at Kow Swamp in Australia. Similar developments could have occurred in other parts of the world (Tobias and Rightmire 2006).

The presumed interrelation of cultural accomplishment and the shape and size of teeth, brain, and jaws is purely theoretical, and not all paleoanthropologists support this connection (Tobias and Rightmire 2006). Throughout the human fossil evidence, there are examples of disconnection between size and shape of skull on the one hand and cultural accomplishment on the other. For example, a smaller-brained *H. erectus* may have been among the first humans to domesticate fire, but a lot bigger-brained humans in other regions of the world living later in time have left no evidence that they used fire. Gradualism is at the core of the so-called “multiregional” hypothesis, in which it is theorized that *H. erectus* evolved into *Homo sapiens* not once but sometimes as each subspecies of *H. erectus*, living in its own region, passed some postulated crucial gateway.

### Theories of Punctuated Change

An ongoing transition from *H. erectus* to *Homo sapiens* is one explanation of the fossil evidence, but the evidence also can be read differently. Some researchers propose what can be termed an accentuated view of human evolution (Tobias and Rightmire 2006). This view suggests that species such as *H. erectus* may have demonstrated little or no morphological alteration over long periods of time (evolutionary stasis) and that the shift from one species to a descendant form may have occurred comparatively quickly and in a restricted geographic region rather than on a universal foundation. Whether any *Homo* species, including our own, evolved slowly or rapidly has not been definitively determined; this underlines the need for many more fossils to establish the assortment of physical variation of *H. erectus* and to allow more exact dating.

## Conclusion

In the study of modern human origins, *Homo erectus* is tremendously important. The Middle Pleistocene was where the modern human post-crania developed, the modern cranial features began to develop, and substantial enhancement in brain size occurred. It is also significant because many behavioral changes took place in this time era, for example, tool use, the controlled use of fire, meat-eating, hunting, etc. This is where the things people consider “human” started to develop to the point where most people would recognize these patterns of anatomy and behavior as similar to our own species.

## Homo ergaster

Ian Tattersall

Division of Anthropology, American Museum of Natural History, New York, NY, USA

## Definition

An early species within the genus *Homo*.

## Introduction

*Homo ergaster* (“work man,” reflecting the presumed associated stone tools) is the nomen applied by Colin Groves and Vaclav Mazak to the pair of associated hominin hemimandibles catalogued in the Kenya National Museums as KNM-ER 992 (Groves and Mazak 1975). Found at Ileret in the East Turkana region of northern Kenya, and dated to about 1.5 Ma, ER 992 had initially been discovered by Richard Leakey in 1971; and when Leakey described the fossils, he allocated them simply to *Homo* sp. (Leakey 1971). At the time, ER 992 was notable among East Turkana hominin finds for its narrow, gracile mandibular corpuses and the modest proportions of its cheek teeth. And its recovery, early in the spectacular sequence of East Turkana discoveries that was made in the decade following 1968,

marked the first in a series of findings that many paleoanthropologists at the time saw fit to compare with the (much younger) *Homo erectus* from Java and eastern China. At the time, however, official policy at East Turkana was to remain vague, and to refer to any clearly non-australopith hominids simply as *Homo*, species unspecified. “Australopiths,” by the way, is the informal name given to the archaically proportioned hominin group from which it is believed our genus *Homo* emerged.

## Systematics

The discovery of the gracile ER 992 mandible slightly preceded the nearby recovery of the cranium ER 3733 and the calotte ER 3883, the somewhat older fossils that caused many to conclude that here was something much closer to later species of *Homo* than anything else known from East Turkana. The main influencing factor seems to have been brain size: at 848 and 804 ml, respectively, endocranial volumes were not far below that of classic Javan *Homo erectus* (the Trinil type specimen comes in at about 950 ml). For reference, australopith brain volumes center around 450 ml, and modern *Homo sapiens* centers on 1330 ml: Holloway et al. 2004). Eventually, Richard Leakey and Alan Walker formally capitulated and allocated all these East Turkana specimens to *Homo erectus* (Leakey and Walker 1976), despite the fact that the specimens (<1.6 Ma) were not only about a million years older than the Javan type material, but did not share any notable cranial morphologies with them.

The argument for “early African *Homo erectus*” seemed to be triumphantly substantiated by the 1984 discovery at Nariokotome, in West Turkana, of KNM-WT 15000, the “Nariokotome Boy.” WT 15000 is a remarkably well preserved ~1.6 myr-old skeleton of an adolescent individual whose brain volume was already 880 ml (headed for an estimated 909 ml had he survived to adulthood), and whose overall body proportions, revealed for the first time, were clearly much closer to those of *Homo sapiens* than to anything else of comparable age (Walker and Leakey 1978, 1993). Whatever one’s view of the proper

identification of these various Turkana specimens (which may in the end prove to represent more than one species), there can be little doubt that these fossils form a coherent grouping, and that they are the earliest hominins that can be included within a morphologically coherent genus *Homo*. In contrast, the inclusion within our genus of anything that has been allocated to the poorly defined “*Homo habilis*” group (and indeed, anything earlier) is questionable.

Ever since *Homo* (then *Pithecanthropus*) *erectus* was described from Trinil by Eugene Dubois during the 1890s, the boundaries of Dubois’s species have been steadily expanded by the inclusion of new specimens. Within the limits of eastern Asia, this expansion seems to be reasonable; but nothing outside this geographical region, either in Europe or in Africa, shares the peculiar features of cranial morphology (long, flat, low braincase with sharp angulation at the back, and shelf-like supraorbital region at the front) that characterize the type material (Schwartz and Tattersall 2000). On the other hand, while one can undoubtedly draw morphological distinctions among the east African materials (ER 992, 3733, 3883, WT 15000, and so forth) that have been included in “early African *Homo erectus*,” it seems at least heuristically useful for the moment to be able to refer to them all by Groves and Mazak’s name *Homo ergaster*. In this view, *Homo ergaster* is the stem species of our genus *Homo*, best documented in East Africa but very possibly also represented in the fossil record elsewhere in the continent; and it gave rise to later species of our genus both in Africa, and widely across the Old World.

Those ancient species would have included *Homo erectus*, which is most plausibly a local and terminal development in eastern Asia. Back in the late nineteenth and early twentieth centuries, with only a few Neanderthal fossils otherwise known to document human evolution, it might have seemed entirely reasonable to view *Homo erectus* as a “stage” within a linear human evolutionary framework: a stage that would almost by definition have embraced precursors in Africa and Europe as well as Asia; but by now, it is clear that the evolutionary history of our subfamily has not been the simple story of gradual refinement of a central lineage over the eons that this scenario

envisions. Instead, the evolutionary pattern we see within the hominins (and within the genus *Homo*) has been pretty typical for any successful mammal group. It clearly involved vigorous experimentation with the hominid potential via the generation of multiple species, each of which had to do battle for ecological space on a Pleistocene stage that was marked by notably fluctuating environments.

Sadly, the paleoanthropological mindset remains linear enough that one still hears a lot about “African *Homo erectus*.” So be sure you know to what fossils the author is referring whenever you see the species mentioned in the literature. Nonetheless, Groves and Mazak’s naming of *Homo ergaster* does offer significant possibilities for freeing human phylogeny from the linear grip in which it has existed for well over half a century; and the auguries are reasonably good for having a more realistic taxonomic framework for the genus *Homo* in the foreseeable future.

## Archaeology and Behavior

Meanwhile, if we take *Homo ergaster* as the initial species of the genus *Homo*, or something close to it, we can begin to come up with a coherent account of how our unusual lineage emerged. Most significantly, *Homo ergaster* lies early in the trend toward increasing brain size that characterized the genus *Homo* throughout the Pleistocene (small-brained and relatively recent forms such as *floresiensis* and *naledi* should probably be excluded from our genus). Two other key things are also clear from the body build of WT 15000. First, *Homo ergaster* had finally abandoned the partly arboreal australopith way of life, and as an obligate biped it had committed itself to life in more open savanna environments. Second, the relatively slender trunk structure of *Homo ergaster* indicates a reduction in the size of the gut. Putting these two observations together, Wrangham (2009) has argued that hunting and the use of fire would have been necessary to support the radically new lifestyle.

Brains are energy-hungry organs; and although animal fats and proteins were (hazardously) available on the savanna in the form of animal carcasses, along with small vertebrates that could be

hunted, the energy they contain remains physiologically relatively unavailable to a creature without a specialized predatory gut – until they are cooked. Cooking with fire would have increased the energy yields from animal and plant products alike, as well as detoxifying them; and the control of fire would additionally have helped early hominins to protect themselves from the numerous predators and scavengers with which they competed. This is a circumstantial argument for the early use of fire by *Homo ergaster*; but it is quite a persuasive one, at least until one considers that the earliest evidence of the control of fire in hearths comes from only around one million years ago – almost a million years after the initial hominin occupation of the savanna. It is possible that the lack of early physical evidence for fire use is due to the fragility of that evidence; but at present, the jury must remain out on this one.

Still, it remains true that members of *Homo ergaster* had significantly larger brains than those of the australopiths; and this fact must have been reflected in some aspects of both cognition and behavior. By the time that *Homo ergaster* appeared, at ~1.8 Ma, the physically archaic australopiths had been making simple “Oldowan” stone tools – mainly simple sharp cutting flakes and crude “pounding” implements – for the best part of a million years, and possibly a good bit longer. Yet, despite all of its physical novelties, *Homo ergaster* continued to make stone tools in the exact same tradition. With a single outlier at 1.78 Ma, we do not commonly find the more complex “Acheulean” handaxes in the East African archaeological record until about 1.6 Ma. This is not actually surprising – *Homo* evidently emerged among the australopiths, and new species and new technologies have never appeared hand-in-hand in the hominid record – but it does mean that we have no material record of any cognitive and behavioral innovations that may have accompanied the new anatomy, and probably more importantly, the new environment. It seems intuitively reasonable to believe that “intelligence” as somehow defined scaled positively with brain size, and that it played a leading role in the time-trend toward larger brains in the genus *Homo*; but it is impossible to specify exactly what “intelligence” implies in this context.

Still, the handaxe clearly represented a major leap in technological complexity and concept. The Oldowan tools of the australopiths (which continued to be made) were mainly sharp flakes, whose main attribute was a cutting edge. It did not matter what they actually looked like, although their manufacture often involved forward planning, stones with the necessary material qualities often being carried several kilometers before being knapped into tools as needed. But the larger handaxe, invented within the tenure of *Homo ergaster*, was conceptually entirely different, involving the elaborate shaping of a stone “core” with multiple blows to both sides until a desired shape – usually that of a teardrop – was obtained. Clearly, tools were now being made to a “mental template” that existed in the mind of the tool-maker before knapping began. The world was beginning to be perceived in a new way.

## Cognition: A Caveat

It is important to understand that the kind of “intelligence” we are looking at in *Homo ergaster* was not a crude variant of modern human symbolic cognition, something that we see emerging only *after* our own species *Homo sapiens* had originated at around 200 Ka. Modern human cognition involves an entirely unprecedented way of manipulating information in the mind; and its acquisition was actually followed by a *reduction* in brain size (Tattersall 2018). What *Homo ergaster* does give us is a glimpse of the very early stages of the evolution of the intuitive, non-declarative, mode of hominin intelligence that preceded the adoption of the symbolic algorithm. It is this type of intelligence that may well have scaled with brain volume, driving the parallel increases in brain size that we see over the Pleistocene in several different lineages within the genus *Homo*.

*Homo floresiensis* is an extinct hominin species that survived on the Indonesian island of Flores during the Pleistocene Epoch. Skeletal remains of *Homo floresiensis* were first discovered during archaeological excavations in the early 2000s at Liang Bua, a large limestone cave located on the western part of the island (Morwood et al. 2004). This species is characterized by small body and

brain size, as well as a combination of primitive and derived traits not seen in other hominin taxa (Brown et al. 2004; Morwood et al. 2005).

## Holotype

The holotype of this species is known as Liang Bua 1 (LB1) and consists of the partial skeleton of an adult. Its official repository in the National Research Center for Archaeology is in Jakarta, Indonesia. Preserved elements include a cranium, mandible, atlas and other vertebral fragments, ribs, right clavicle, right humerus, left and right ulna, left and right hip bones, left and right femora, left and right patella, left and right tibiae, left and right fibula, and a number of hand and foot bones. During life, this individual would have stood ~106 cm tall and weighed ~27.5 kg (Grabowski et al. 2015). The cranium is strikingly small in comparison to other species in the genus *Homo*, and its brain size is estimated at ~420 cm<sup>3</sup>, roughly one-third the size of the brain in modern humans (*Homo sapiens*). The endocast is similar in overall shape to that of Asian *Homo erectus*, but also displays some uniquely derived features (e.g., extremely wide temporal lobes, expansions in the frontal polar region, and position of the lunate sulcus) that are suggestive of higher cognitive processing capabilities (Falk et al. 2005). The anatomy of the hip and lower limb bones, as well as that of the vertebrae and the position of the foramen magnum on the cranium, indicate terrestrial bipedality as the principal mode of locomotion. However, the length proportions of the upper to lower limbs, and a foot that is long relative to the leg, suggest that this species would have been more proficient in climbing, rather than running, in comparison to modern humans (Jungers et al. 2009).

## Other Individuals

Skeletal remains of several other *Homo floresiensis* individuals have also been recovered from Liang Bua. These include: a right ulna and mandibular third premolar (LB2); a left radius (LB3); a juvenile left radius and right tibia

(LB4); an atlas (LB5); a mandible, right scapula, right radius, left ulna, and multiple hand and foot bones (LB6); a right tibia (LB8); a pollical proximal phalanx (LB10); and a right mandibular fourth premolar and left maxillary central incisor (LB15).

## Age

All skeletal elements and stone artifacts attributed to *Homo floresiensis* are stratigraphically overlain by volcanic tephra T1 and T3, respectively. Based on a combination of dating methods that includes infrared stimulated luminescence, thermoluminescence, uranium series (<sup>234</sup>U/<sup>230</sup>Th), and <sup>40</sup>Ar/<sup>39</sup>Ar, T1, and T3 are estimated to be ~60 and 50 thousand years (ka) old, respectively. In addition, direct <sup>234</sup>U/<sup>230</sup>Th dating of ulnae from three *Homo floresiensis* individuals gave modeled ages ( $\pm 2\sigma$ ) ranging from  $86.9 \pm 7.9$  to  $71.5 \pm 4.3$  ka (LB1),  $71.4 \pm 1.1$  to  $66.7 \pm 0.8$  ka (LB2), and  $66.0 \pm 4.3$  to  $54.6 \pm 2.1$  ka (LB6), all of which reflect minimum ages of deposition. Thus, the current chronological evidence suggests that the skeletal remains of *Homo floresiensis* are likely between ~100 and 60 ka old, and stone artifacts reasonably attributable to this species range in age from ~190 to 50 ka (Sutikna et al. 2016).

## Stone Artifacts

Tens of thousands of stone artifacts made by *Homo floresiensis* have been recovered at Liang Bua. These artifacts are mostly the result of free-hand hard-hammer percussion, where a hammer stone held in one hand is forcefully struck against a stone held by the other hand, although burination, truncation, and bipolar techniques were also used. Various studies of this artifact assemblage have shown that it shares broad similarities in both morphology and technology with Oldowan assemblages in eastern Africa (Oldowan artifacts are the simplest form of stone tools produced by freehand hard-hammer percussion), as well as with Early and Middle Pleistocene assemblages elsewhere on Flores (Moore et al. 2009).

## Ecology

*Homo floresiensis* lived alongside Komodo dragons (*Varanus komodoensis*), a proboscidean (*Stegodon florensis insularis*), and two large carnivorous birds, giant marabou stork (*Leptoptilos robustus*) and vulture (*Trigonoceps* sp.), along with a variety of smaller animals (mostly rats and bats) with body masses less than ~3 kg (Sutikna et al. 2018).

## Phylogeny

*Homo floresiensis* is almost certainly a descendant species of an ancient hominin lineage that was present in Asia before the estimated time of divergence (~765–550 ka ago) of the lineages that ultimately led to the evolution of Neanderthals and Denisovans in Eurasia, as well as modern humans in Africa. This ancient ancestral lineage is probably the result of an earlier hominin dispersal from Africa more than ~1.5 million years ago. The ancestor of *Homo floresiensis* (or the species itself) likely arrived on Flores by at least one million years ago, based on the presence of stone artifacts at sites in central Flores and ~700 ka old *Homo floresiensis*-like teeth and lower jaw fragments discovered in this area (Brumm et al. 2016). Hypotheses explaining the origin and evolution of *Homo floresiensis* often take the form of one of two possibilities: (1) this taxon is a descendant species of Asian *Homo erectus*, and the smaller body and brain size of *Homo floresiensis* probably evolved in isolation on Flores; or (2) *Homo floresiensis* is a descendant species of another premodern taxon of *Homo* that was smaller bodied and smaller brained when it first reached Flores. Each of these hypotheses is supported by a different combination of the available evidence, and further discoveries are needed to resolve which, if either, is correct.

## Homo heidelbergensis

Laura T. Buck

Research Centre in Evolutionary Anthropology  
and Palaeoecology, Liverpool John Moores  
University, Liverpool, UK

### Definition

A controversial Middle Pleistocene (~780–130 ka) hominin species, part of the same genus (*Homo*) as extant humans.

### Introduction

The taxonomy and phylogeny of *Homo heidelbergensis* is much debated (for a review see Stringer 2012), so much so that this period in human evolution has been dubbed the “muddle in the Middle [Pleistocene].” There is little agreement on which specimens should be included in *H. heidelbergensis* (that is to say, the group of specimens which constitute what is known as its “hypodigm”), nor even whether it constitutes a valid species at all. Many Middle Pleistocene hominins (taxa more closely related to *H. sapiens* than to chimpanzees) share primitive features with earlier species, such as *H. erectus*, but also share derived traits with later Pleistocene specimens such as *H. sapiens* and Neanderthals (e.g., Rightmire 2013). This mosaic morphology has led researchers to group them together as a single Afro-European species designation: *H. heidelbergensis*. Some have also suggested that additional Asian Middle Pleistocene fossils may extend the range of *H. heidelbergensis* (e.g., Stringer 2012). One reason for the great interest in *H. heidelbergensis* is that the Middle Pleistocene is the epoch during which the *H. sapiens* lineage split from our sister taxa, the Neanderthals and Denisovans, and *H. heidelbergensis* has long been considered a possible last common ancestor (LCA) for these two lineages (Buck and Stringer 2014; Mounier et al. 2009; Rightmire 2008; Stringer 2012). Knowing the identity of the LCA

would allow us to see which differences between our own species and Neanderthals are derived in which lineage, enabling us to better understand our own evolution and that of our closest relatives.

### What Is *H. heidelbergensis*?

The name *H. heidelbergensis* comes from the Mauer mandible, a ~600 ka (1000 year old) fossil found near Heidelberg, Germany, in 1907. This remarkably robust mandible is the type specimen for *H. heidelbergensis*, the specimen against which all potential members of the species must be compared. This means that no hypodigm can be called *H. heidelbergensis* without the inclusion of the Mauer mandible. The size and robusticity of the Mauer mandible are reminiscent of *H. erectus*, yet it is much younger than any European *H. erectus* and also displays characteristics linking it to later taxa, such as smaller teeth (Stringer 2012). There are similarities between the Mauer mandible and a mandible from Arago (France, ~400 ka) and a partial cranium from Arago shows affinities with Middle Pleistocene fossils from elsewhere in Europe and Africa, allowing the entire hypodigm to be designated *H. heidelbergensis* (Mounier et al. 2009; Rightmire 2008).

The use of a mandible for the important role of type specimen has complicated our understanding of *H. heidelbergensis* (Stringer 2012). Few mandibular fossils are known from the Middle Pleistocene, making it hard to link specimens from different sites with the Mauer mandible and thus with the species designation *H. heidelbergensis*. Furthermore, there are fewer diagnostic traits on the hominin mandible than the cranium, making it a less reliable region for dividing taxa. Comparative shape analysis of Mauer and other Middle Pleistocene mandibles supports an Afro-European species diagnosis of *H. heidelbergensis* (Mounier et al. 2009), but this depends on the hypodigm. If Spanish material from the site of Sima de los Huesos is excluded, based on recent reinterpretations of these fossils as early Neanderthals, there is less evidence for linking the Mauer mandible to the rest of the

hypodigm (Stringer 2012). It has been suggested that the Mauer mandible should be discarded as the type specimen for *H. heidelbergensis* (Hublin 2009), in which case the name *H. rhodesiensis* (taken from the fossil Kabwe from Zambia, previously Rhodesia) would probably be applied to an Afro-European taxon combining Middle Pleistocene material such as Bodo, Kabwe, and Petralona (Fig. 1) (Buck and Stringer 2014; Stringer 2012; Thackeray et al. 2020). For clarity, the designation *H. heidelbergensis* will be used here throughout to describe this general hypodigm.

### What Are the Characteristics of *H. heidelbergensis*?

Middle Pleistocene fossils diagnosed as *H. heidelbergensis* (Fig. 1) exhibit a combination of primitive, *H. erectus*-like, features with those that are derived compared to *H. erectus* and are found in chronologically younger taxa. Primitive characteristics of this group include the occipital morphology, wide interorbital breadth, and large browridges, while more derived features include greater brain volumes, the basicranial morphology, and reduced facial projection (Rightmire

**Homo heidelbergensis, Fig. 1** *H. heidelbergensis* fossils. Three of the most iconic potential *H. heidelbergensis* specimens (left to right): Kabwe (Broken Hill) from Zambia dated to ~300 ka, Bodo from Ethiopia dated to ~600 ka, and Petralona from Greece dated to ~400 ka. From top to bottom, images are of front, top, and side views of crania. (Images are of virtual

models created using CT data, courtesy of the Natural History Museum (London), University of Vienna and University of Thessaloniki, respectively). The side view of Kabwe has been mirrored horizontally for consistency as the right side of the fossil is better preserved. Images have been approximately scaled to equal size for better comparison

2008, 2013). There is, however, much variation within the group, even within geographical regions. Many species show considerable variation due to factors such as sexual dimorphism, adaptation to local environments, and population history and opinions differ as to whether the levels of variation within the *H. heidelbergensis* hypodigm exceed those plausible for a single species (Lacruz et al. 2019; Mounier et al. 2009; Rightmire 2008; Stringer 2012).

Archaeological sites attributed to *H. heidelbergensis*, such as Boxgrove (UK, ~500 ka), have yielded rich lithic assemblages including beautiful Acheulian handaxes (Roberts et al. 1999). Organic remains of this ancient are rarely preserved, but extraordinary wooden artifacts, possible spears, from the sties of Clacton (UK, ~400 ka (Allington-Jones 2015)) and Schöningen (Germany, ~300 ka (Conard et al. 2015)) hint at considerable technological and hunting sophistication during this epoch. The Middle Pleistocene

also sees the first good evidence for control of fire, with the remains of clear hearths at sites such as Beeches Pit (UK, ~400 ka) (Roebroeks and Villa 2011). This archaeology provides insights into how these hominins were able to colonize high latitude regions of Europe during the Middle Pleistocene.

## The Role of *H. heidelbergensis* in Human Evolution

For some time, *H. heidelbergensis* has been widely thought of as the possible LCA of *H. sapiens* and Neanderthals (Fig. 2). *H. heidelbergensis* is a suitable candidate for this role as the *H. sapiens* and Neanderthal/Denisovan lineages diverged in the Middle Pleistocene and potential *H. heidelbergensis* fossils are found in both Africa, the birthplace of *H. sapiens*, and Europe, the birthplace of Neanderthals. Depending on the

**Homo heidelbergensis, Fig. 2** Possible position for *H. heidelbergensis* in the phylogeny of mid-late genus *Homo*. Three main hypotheses for the taxonomic position of *H. heidelbergensis*. Time is on the left-hand axis, Ma: millions of years ago, ka: thousands of years ago. (a) European *H. heidelbergensis* as ancestral to

Neanderthals (*H. neanderthalensis*) and the related Denisovans, while African Middle Pleistocene specimens are placed in *H. rhodesiensis*; (b) *H. heidelbergensis* is the last common ancestor of *H. sapiens*, Neanderthals and the related Denisovans; (c) *H. heidelbergensis* as not directly ancestral to either *H. sapiens* or Neanderthals

hypodigm favored, *H. heidelbergensis* also shows cranial expansion and facial characteristics that can be argued to foreshadow the morphology of both *H. sapiens* and Neanderthals (Buck and Stringer 2014; Mounier et al. 2009; Rightmire 2008; Stringer 2012; Thackeray et al. 2020).

An alternative viewpoint for many years has been that *H. heidelbergensis* was limited to Europe, where it was ancestral to the Neanderthals alone (e.g., Dean et al. 1998) (Fig. 2). In this scenario, Middle Pleistocene African fossils formed part of another taxon, most likely *H. rhodesiensis*. This hypothesis relied heavily on the inclusion in *H. heidelbergensis* of fossils from the Spanish site of Sima de los Huesos, since these specimens show many Neanderthal characteristics, placing them firmly on the Neanderthal lineage. The redating of the Sima de los Huesos fossils from ~600 to ~430 ka (Arsuaga et al. 2014) has convinced many that they are best interpreted as early Neanderthals, rather than *H. heidelbergensis*, reducing support for exclusively European *H. heidelbergensis* (Buck and Stringer 2014; Stringer 2012). The presence of some Middle Pleistocene European fossils lacking Neanderthal characteristics, such as Ceprano (Italy, ~430 ka), and no clear chronological sequence in the development of Neanderthal morphology, may instead indicate taxonomic complexity and the coexistence of multiple lineages (Martín-Torres et al. 2012; Bermúdez-de-Castro et al. 2016).

## Changing Places: Recent Developments

The iconic cranium from Kabwe (Broken Hill) has been pivotal to discussions of *H. heidelbergensis*, in part due to its similarities with Petralona from Greece, which support the taxon's Afro-European distribution (e.g., Harvati et al. 2010; Stringer 2012). Recent work has, however, begun to undermine the status of this fossil as a representative of the LCA of *H. sapiens* and Neanderthals. Since its discovery in 1921, Kabwe has been difficult to date precisely and it was given an indirect approximation of ~700–300 ka, which made it a reasonable

candidate for a member of the LCA (Klein 1973). After years of reanalysis, Kabwe has now been directly dated to about 300 ka ( $299 \pm 25$  ka) (Grün et al. 2020). Recent work shows that some characteristically *H. sapiens* features are already present at ~300 ka at sites such as Jebel Irhoud in Morocco (Richter et al. 2017) and the same is true of Neanderthal features in European fossils from ~400 ka onwards (e.g., Sima de los Huesos from Spain, Swanscombe from the UK, and Steinheim from Germany (Dean et al. 1998)). This being the case, Kabwe, which displays no clear Neanderthal or *H. sapiens*-derived morphology, is less convincing as a representative of the LCA. Earlier potential *H. heidelbergensis*, such as Bodo (~600 ka), are chronologically possible representatives of the LCA, but with split times for *H. sapiens* and Neanderthal lineages based on aDNA modeling at ~600 ka (Meyer et al. 2016), an older taxon is also plausible.

An alternative LCA is *H. antecessor*, a species known only from the Early Pleistocene (~860 ka) site of Gran Dolina, Spain (Bermúdez-de-Castro et al. 2017; Stringer 2016). *H. sapiens* is peculiar amongst hominins in its small, vertically orientated face (Lacruz et al. 2019; Stringer and Buck 2014). A fairly complete juvenile face from Gran Dolina appears to have distinctively *H. sapiens*-like morphology, suggesting it could be part of our lineage, while in other characteristics *H. antecessor* fossils resemble Neanderthals (Bermúdez-de-Castro et al. 2017). An *H. sapiens*-like face in *H. antecessor* suggests the facial morphology of the LCA was preserved in the human lineage, while Neanderthal morphology diverged (Lacruz et al. 2019). The young developmental age of the crucial *H. antecessor* fossil was initially a concern, but computer modeling, which virtually aged the fossil along different potential growth trajectories, supported the assertion that its diagnostic morphology would have been retained into adulthood (Freidline et al. 2013). Microscopic examination of juvenile fossil bone surfaces is also suggestive. These analyses reveal patterns of areas where bone is either laid down or sculpted away, producing characteristic adult shape over the course of development. Of all the hominin taxa currently

investigated, only *H. antecessor* seems to have a *H. sapiens*-like facial growth pattern (Lacruz et al. 2013, 2019). The facial evidence thus supports the hypothesis that *H. sapiens*-like morphology was already present in *H. antecessor*, the potential LCA, during the Early Pleistocene (~1800–780 ka) and was preserved in its descendent, *H. sapiens*. Those who take this viewpoint do not necessarily discount the validity of *H. heidelbergensis* as a species, but suggest it is tangential to the evolution of *H. sapiens* and Neanderthals (Lacruz et al. 2019).

## Conclusion

Recent years have to some extent clarified the “muddle in the Middle” and evidence is building that *H. heidelbergensis* may not be the LCA of *H. sapiens* and Neanderthals. Whether it is a valid species and what constitutes its hypodigm if so, however, is still an open question. Indeed, there is growing recognition in Paleoanthropology that strict species designations are human constructs that only approximate biological reality and can be particularly problematic when applied to the fossil record e.g., (Thackeray et al. 2020).

There is strong morphological evidence that at least some African and European Middle Pleistocene fossils can be combined in a hypodigm, which in the absence of mandibular evidence for the key specimens is probably best referred to as *H. rhodesiensis* (Stringer 2012). Asian Middle Pleistocene fossil material has been to some extent overlooked during this discussion and the addition of Asian fossils to this hypodigm is also still possible. One key example is the newly announced cranium from Harbin, China. This specimen appears to have similarities to the Afro-European hypodigm, but it has yet to be formally described (Lacruz et al. 2019). A number of other new discoveries, or new dates, of crania from sites such as Harbin, Auerira (Portugal; Daura et al. 2017), and Apidima (Greece; Harvati et al. 2019) show increasing evidence of taxonomic complexity in the genus *Homo* during the Middle Pleistocene and multiple taxa seem likely in several regions (Martín-

Torres et al. 2012; Rak et al. 2011). Advances in aDNA research may help to unpick the relationships between Middle Pleistocene taxa. Genetic material has been sequenced from the ~430 ka Sima de los Huesos fossils, supporting their close relationship with Neanderthals and showing that Middle Pleistocene DNA can be successfully retrieved and analyzed (Meyer et al. 2016). Recent work shows the introgression of DNA from “ghost” taxa (hominins of unknown taxonomic designation, perhaps those for which there is no known fossil evidence as yet) into both *H. sapiens* and extinct species, such as the Denisovans (Wolf and Akey 2018). Perhaps better understanding of these ghosts, as well as additional aDNA recovery from fossils, will illuminate the true nature of *H. heidelbergensis*.

## Synonyms

Anatomically modern humans (AMH); Human  
being; Modern human

Definition

The binomen *Homo sapiens* is composed of the genus name *Homo* (“human being” in Latin) and the species name *sapiens* (“wise”), and it designates all living humans (and their extinct direct relatives). According to the fossil record, the origin of *Homo sapiens* is around 200,000 to 300,000 years ago in Africa. Today, it is the only existing species of the genus *Homo*, which in the past included numerous species now extinct (e.g., *Homo habilis*, *H. erectus*, *H. neanderthalensis*, etc.).

Introduction

The species name *Homo sapiens* was invented by C. Linnaeus in 1758, in the 10th edition of his *Systema Naturae*, to accommodate all living humans. In the late eighteenth and early nineteenth century, fossil representatives and extinct species of the genus *Homo* were not known, and in a fixist (i.e., non-evolutionist) context, *Homo sapiens* was thought to be the only human species that ever existed. Accordingly, its original description by Linnaeus was minimalist, consisting only in the famous – but not very informative – “*Nosce Te Ipsum*” (“Know Thyself”). For obvious reasons, no type specimen (or “holotype,” the reference specimen of the species) has ever been designated for *Homo sapiens*, and it is today the only valid species with no holotype. Indeed, we all know that all of us actually belong to the same species. But, together with the absence of a clear morphological definition of the species, it contributes to make the attribution of fossil specimens more complicated.

Among mammals, *Homo sapiens* belongs to the order primates. It is one of the c. 300 known living species of primates, and our closest living relatives are the two chimpanzee species: the common chimpanzee (*Pan troglodytes*) and the bonobo (*Pan paniscus*). One of the most frequently used taxonomies (Table 1) places *Homo sapiens* in the tribe Hominini, a subdivision of the family Hominidae. The family Hominidae includes all extant great apes (orangutans,

**Homo sapiens, Table 1** Taxonomy of the family Hominidae at the genus level, including extinct hominins (indicated by †). This is one option among the various currently accepted taxonomies for Hominidae. This taxonomy does not include fossil genera for tribes other than hominins, nor of the extinct tribe of Eurasian apes Dryopithecini, in the subfamily Homininae

gorillas, chimpanzees, and humans) and their extinct relatives. The tribe Hominini (“hominins”) includes humans and chimpanzees, although chimpanzees are sometimes placed in a separate tribe called Panini. Hominini also includes all extinct relatives of humans and chimpanzees since their Last Common Ancestor (“LCA”), which according to fossil and genetic evidence lived between c. 10 and 6 million years ago.

Since the mid-nineteenth century, discoveries made in the fields of palaeoanthropology and prehistory document a very rich and long evolutionary history for the hominins. This is especially true for the branches of the evolutionary tree where the genera *Australopithecus* and *Homo* are found. Abundant fossils corresponding to several distinct extinct species have been recognized in those two genera, indicating that *Australopithecus* lived from about 4.4 to 1.9 million years ago and *Homo* from 2.8 million years ago until today. The manufacture of stone tools had for a longtime been directly and exclusively linked in the definition of the genus *Homo*. However, in recent years, several discoveries broke this certainty, like the discovery of animal bones with cutmarks or percussion points (and thus

indirectly showing the use of stone tools) close to remains of *Australopithecus* (*A. afarensis*, *A. garhi*), before the recent finding of 3.3 million-year-old large stone tools (anvils, nucleus, flakes at Lomekwi, Kenya; Harmand et al. 2015). These discoveries indicate that the production and use of stone tools appeared several hundred thousand years before the emergence of *Homo* and are thus probably linked/associated to *Australopithecus*-like hominins. To the contrary, the evolutionary history of the chimpanzees since the LCA is still poorly documented in the fossil record, and the very early stages of the evolution of the hominins remain to be understood. At the end of the 1990s and early 2000s, fossils dated to between c. 7 and 4 million years ago have been discovered. They correspond to three genera (*Sahelanthropus*, *Orrorin*, and *Ardipithecus*) which show indices of upright posture and bipedal locomotor behavior, i.e., one of the main “human” features. No archaeological evidence of any technical behavior (i.e., tools) is associated to these three genera. However, some authors argue that the use and/or production of stone tools by nonhuman great apes like chimpanzees could indicate that this cultural (material culture) trait may have been shared by very ancient hominins.

Most of the evolutionary history of the hominins took place in Africa, until some human groups went out of Africa for the first time, probably at around two million years ago or even earlier. The origin of *H. sapiens* is also African, as indicated by genetic and fossil evidence. The oldest fossils currently described as “fully *H. sapiens*” have been found in Ethiopia and are dated to c. 200,000 years ago (McDougall et al. 2005). Recent studies of fossils found at Jebel Irhoud (Morocco) indicate that “*Homo sapiens*-like” hominins were present in Northern Africa by at least 300,000 years ago (Hublin et al. 2017). Those fossils lack very few anatomical features to be considered as anatomically modern humans (AMH) and revive the debate on the exact list of anatomical features defining *H. sapiens*. If we have a fairly good knowledge of the variation of the morphological traits of present-day *H. sapiens*, several fossils found in Africa and Asia, for instance, show that the

morphological and genetic diversity of our species was larger in the Upper Pleistocene than it is today. This is also true for cultural or behavioral features. For years, *H. sapiens* was archaeologically defined by a set of elements constituting the so-called modern behavior (e.g., complex hunting weapons, symbolic behaviors). However, new discoveries and new studies show that, in the past, it is quite difficult to identify clear differences between *H. sapiens* and other closely related and/or contemporaneous species such as *H. neanderthalensis*. It is also challenging because extant humans, who stand as the reference point for comparisons, appear to be extremely diverse in their biological, cultural, and behavioral attributes.

## **Homo sapiens Today**

### **We Are All Homo sapiens**

Whatever the region of the world in which we live today, we all belong to one and the same species, *Homo sapiens*. However, compared to other animal species – including our closest living relatives in the primate order – *H. sapiens* has a huge geographical range, it occupies a very wide range of habitats, and it is an extremely diverse species. Observing human groups living today in various places of the world, there is a considerable amount of biological, cultural, and behavioral variation. Accordingly, if there is no doubt about the fact that we all belong to the same species, to give a consensual definition of this species is a complicated task.

### **How to Recognize a Living Homo sapiens**

*H. sapiens* is often defined as a primate with a bipedal gait and erect posture, endowed with culture, making and using tools, and capable of empathy and emotions. Although, taken one by one, none of these features are actually exclusive to *H. sapiens*, their combination is probably unique. Anatomically, *H. sapiens* is also distinguished from its closest living relatives by a large brain relative to body mass, a face that is reduced in size and not projected forward, a modified vocal tract (involved in spoken language), body

proportions (e.g., long legs relative to arms), hands with opposable thumb and abilities of precision grip and manipulation, reduced hairiness, and pigmented skin. Several of these physical attributes (e.g., body proportions, skin pigmentation) can show a large range of variation in the species under the influence of environmental factors such as altitude and sun exposure. Sexual dimorphism, i.e., the difference in size and shape between males and females, is reduced in *H. sapiens*. This characteristic is linked to the fact that human social groups are based on cooperation rather than on competition between males for access to females, differing from many other primate species in which males are much larger than females. In an evolutionary perspective, it is often considered that the combination of all those anatomical features defines “anatomically modern humans” (AMH), although the use of “modernity” in a biological sense is questionable and is a frequent source of confusion with socio-cultural considerations.

Extended childhood – the period of time during which an offspring is not able to care for itself – is also an important characteristic of *H. sapiens*, although its time of appearance in the evolutionary history of hominins is debated. It is linked to a hypothesis called the “obstetrical dilemma” by Washburn in 1960, who argues that “adaptation to bipedal locomotion decreased the size of the bony birth-canal at the same time that the exigencies of tool use selected for larger brains. This obstetrical dilemma was solved by the delivery of the fetus at a much earlier stage of development” (Washburn 1960: 74). The evolutionary answer to this dilemma is to give birth to “highly immature children.” This implies prolonged growth and learning period, which have important consequences on human social structures (unavailability of the mother for reproduction, cooperation among adults to take care of the children, etc.).

### ***Homo sapiens*: A (Hyper)social Species?**

In the behavioral and cognitive fields, *H. sapiens* is also characterized by a large variability, even if a large part of human social traits are shared with other mammals, particularly primates. After all, we share 98% of our genetic pool with other

primates like chimpanzees. And as recent studies highlight, genetic and cultures are intimately linked, or, more exactly, genetic structure proceeds partially from cultural choices and social selection (Richerson et al. 2010). Such examples include stature differences between males and females within human populations, or the different frequencies of genes related to lactase persistency (i.e., highest frequencies in regions where people consume animal milk, linked to the transmission through time of animal domestication and dairying practices).

Generally speaking, extant modern humans belong to very diverse (hyper)social communities, living and evolving in groups which are cohesive in terms of spoken language, material cultures *sensu lato*, or social structure (residence rules, patri- or matrilinear, monandry, polygamy, etc.). From birth, *H. sapiens* is (pre)configured for sociability, which facilitates brain maturation, particularly during childhood, and development of the learning capacities and the social transfer of knowledge mechanisms. Our species is stimulated by its life in community, within territories whose management and exploitation are in themselves factors of morphological and cultural evolution. Some researchers point out, for example, that the *H. sapiens*' success story throughout its tens of thousands of years of dispersal and expansions is largely grounded on its abilities of empathy behaviors, facilitated by the development of a brain sensitive to its social environment. This development of the senses of organization, cooperation, and mutual aid among a social group might have been a major element during times of demographic or environmental crisis.

Together with other brain structural enhancements, resulting, for example, in language and memory skills, these social traits appear as driving forces in the evolution of *H. sapiens*, compared to other primates. The aptitude of early modern humans to adapt to very diverse and contrasted situations in terms of climate and landscape (and more generally in terms of natural and cultural environments) might also have been in itself a factor of innovations. These innovations defined the so-called modern behavioral package of *H. sapiens*, even though the concept of

“modernity” is also questionable here. Nevertheless, this capacity to overcome complex situations by the development of new strategies probably helped AMH to “conquer the whole world” in few tens of thousands of years.

**Homo sapiens in the Past: Origin and Evolutionary History**

**Early Hominins and the Origin of the “Human Lineage”**

The phylogeny of extant hominids (living great apes, including *H. sapiens*) is now resolved, but

it is far from being the case of the whole family Hominidae, with all extinct hominins known today (Fig. 1). Most of the nodes (i.e., “hypothetical ancestors” of two diverging branches), tempo of evolutionary changes of key anatomical features, and detailed phylogenetic relationships remain debated in our family tree. The earliest recognized hominins (the genera *Sahelanthropus*, *Orrorin*, and *Ardipithecus*) have reduced canines and anatomical traits that are generally interpreted as pointing to some degree of terrestrial bipedalism. Those features align them preferentially with *Australopithecus*, *Paranthropus*, and *Homo*, forming the “human

**Homo sapiens, Fig. 1** Chronological extension of the key genera and species of the tribe Hominini, with a simplified tentative phylogeny (chronology is in millions of years ago: Mya; extinct species: gray boxes, extant species: black boxes; divergence times in the phylogeny are purely indicative; adapted and modified from Wood and Boyle 2016). “Denisovans” are indicated by a single star, because they are still known from a very limited number of fossils and no new species name has been formally published for them yet. *Kenyanthropus* is not included in the simplified phylogenetic hypothesis. It is

still a poorly known genus, with a single species (*K. platyops*), but it is possibly the manufacturer of the earliest stone tools known to date (Lomekwi in Kenya, at c. 3.3 Mya, Harmand et al. 2015). Several fossil species are omitted for clarity purposes, or because they are still debated/known from few fossil specimens: *Australopithecus sediba* at c. 2 Mya, *A. deyiremeda* at c. 3.5–3.3 Mya, *A. garhi* at c. 2.5 Mya, *A. bahrelghazali* at c. 3.6 Mya, *Homo georgicus* at c. 1.8 Mya, *H. antecessor* at c. 1.2–0.7 Mya, *H. rhodesiensis* at c. 0.6–0.3 Mya, and *H. naledi* at c. 0.3–0.2 Mya

lineage” characterized by facultative or obligate terrestrial bipedalism, rather than with the chimpanzees which are arboreal and terrestrial knuckle-walkers (knuckle-walking is a specialized type of quadrupedal walking, with ground support of the upper body on flexed manual phalanges). However, the posture and locomotor behaviors of the LCA (between *Pan* and the “human lineage”) remains largely unknown, and the fossil record for *Pan* and its direct ancestors is excessively poor (mainly known from few teeth recovered in Kenya and dated to c. 500,000 years ago). This situation might explain why at the moment *Sahelanthropus*, *Orrorin*, and *Ardipithecus* tend to align more closely to the human lineage which is documented by thousands of fossil remains rather than with the virtually undocumented *Pan* lineage. The genus *Australopithecus* is known from a great number of fossils discovered since the 1920s in Africa. Several distinct species have been recognized based on fossil assemblages recovered from Eastern Africa (e.g., *A. anamensis*, *A. afarensis*, *A. garhi*), Southern Africa (*A. africanus*, *A. sediba*), as well as from Central Africa, in present-day Chad (*A. bahrelghazali*). Among those different species of *Australopithecus*, there is a great deal of interspecific and intraspecific anatomical variation documented in most skeletal parts, including those involved in locomotion. If it points to diversified locomotor behaviors with generally dominant terrestrial bipedalism, it also contributes to complicate the understanding of the exact phylogenetical relationships and evolutionary history of the genus *Australopithecus*, which is most probably paraphyletic (i.e., a composite group of species which share a common ancestor, but not all of its descendants).

Similarly complex and unresolved is the phylogeny of the three commonly recognized species of *Paranthropus*: *P. aethiopicus* and *P. boisei* in Eastern Africa and *A. robustus* in Southern Africa. They are characterized by very large post-canine teeth (i.e., premolars and molars) and a massive masticatory apparatus, and they were previously assigned to the genus *Australopithecus* (the so-called robust *Australopithecines*). For many years now, there are doubts whether those

three species form an actual monophyletic group (i.e., all the descendants of a common ancestor) or if they instead descended independently from different ancestors – different *Australopithecus* species – in Eastern Africa on the one hand and in Southern Africa on the other hand. The actual evolutionary relationships of *Paranthropus* species with the earliest members of the genus *Homo* (*H. habilis* and *H. rudolfensis*), which were living in the same regions of Africa at the same time, also remain poorly understood.

### The Genus *Homo*: A Single Living Species, Numerous Extinct Species

Historically, early members of the genus *Homo*, to which *H. sapiens* belongs, were first discovered by Louis and Mary Leakey in the site of Olduvai, present-day Tanzania, in geological layers dated to c. 1.8 million years ago which also yielded stone tools. In a seminal paper published in 1964, Louis Leakey, Phillip Tobias, and John Napier described the morphology and context of discovery of the fossils and decided to assign them to a new species of the genus *Homo*: *Homo habilis*. But to do so, in the same article, they first had to revise and modify the definition of the genus *Homo* which was generally accepted at the time, but which was too restrictive to accommodate the fossils found in Olduvai. In fact, this definition has been frequently modified and its limits enlarged since the mid-nineteenth century – and especially during the twentieth century – so that the genus *Homo* may include new fossil discoveries assigned to new extinct hominin species. This was the case, for instance, for *H. neanderthalensis* in 1856, for *H. heidelbergensis* in 1908, for *Pithecanthropus erectus* published in 1894 but regarded as *H. erectus* since the 1950s, and for *H. habilis* in 1964, where few pieces of evidence except for their association with stone tools were actually arguing for the attribution of the Olduvai fossils to the genus *Homo* rather than to the genus *Australopithecus*. Until today, the definition of the genus *Homo* is a rather easy task when dealing with living Hominidae only, but remains a much discussed topic in prehistory and palaeoanthropology on which no actual consensus has been reached yet.

Throughout the years, however, the most commonly accepted definition of the genus *Homo* remains based on four criteria: (1) a large absolute brain size (greater than 600 cm<sup>3</sup>), (2) the possession of spoken language, (3) hands with an opposable thumb and precision grip capabilities, and (4) the ability to manufacture stone tools.

This list has been and is still debated for two main reasons. On the one hand, some of those features are obviously difficult to assess from fossil remains, such as the possession of spoken language which is extremely difficult to ascertain only from the study of fossil endocasts. On the other hand, taken one by one, none of these features is actually restricted to members of the genus *Homo*, complicating the task of assigning most – if not all – hominin fossil assemblages to the genus *Homo*. Alternative approaches to this complex issue of the definition of the genus *Homo* have been proposed. In the early 2000s, some palaeoanthropologists considered long-distance (or endurance) running and associated anatomical and physiological traits as being unique to the genus *Homo* (Bramble and Lieberman 2004). At the same time, using only objectively verifiable criteria to test several phylogenetic hypotheses about hominin evolution, other researchers proposed that the genus *Homo* should be restricted and exclude *H. habilis* and *H. rudolfensis* to be an actual monophyletic group (Wood and Collard 1999).

Shortly after two million years ago, hominins expanded out of Africa for the first time and settled in various regions of Eurasia. At c. 1.8 million years ago, some groups were present in the Caucasus (site of Dmanisi, in present-day Georgia) and at about the same time period in East Asia (China). Fossil assemblages indicate that, starting at around 1.6 million years ago, hominins were occupying Southeast Asia (site of Sangiran, Indonesia) and at c. 1.2 million years ago Occidental Europe (site of Sima del Elefante in Atapuerca, Spain). There is no real agreement on how many different species should be recognized for these hominin groups, which were widely dispersed in space and chronology: few different species (or even only one, *H. erectus*) or several.

Although environments and climates can vary dramatically inside the African continent, the vast majority – if not the whole – of the early fossil record for the genus *Homo* known to date in Africa is derived from “Savannah-like” past environments. There are possible biases (e.g., preservation and fossilization conditions, preferentially targeted areas for researches in the field) which could explain this situation, but it seems quite obvious that, after some of them ventured out of Africa and settled in various regions of the Old World, hominins had to cope with very different and very diverse living conditions. Hominins were then occupying territories dispersed on various areas in Africa and Eurasia, implying increased distances between groups and very diverse environmental conditions (temperatures, precipitations, natural resources such as mineral resources for stone tools, animals and plants for consumption, etc.) acting on the natural selection of biological features at a microevolutionary scale. Those factors probably played a major role in driving these groups (or species) along diverging biological and cultural evolutionary paths, resulting in the appearance of various adaptive strategies. A whole area of modern researches in prehistory consists in understanding if the adaptive strategies adopted by those many different species of the genus *Homo* which occupied the Old World in the past were the same as those of *Homo sapiens*, and if not, how and how much they differ from them. Anatomically speaking, comparisons based on the fossil record show that the morphological variation documented between those groups was considerably larger than that of present-day *H. sapiens*.

### **From Cro-Magnon to Omo Kibish: The Earliest Fossil Evidences for *Homo sapiens***

Fossils and genetics indicate that the origin of *H. sapiens* is undoubtedly African. With few hundreds of thousands of years of existence, it is a young species in view of the long – several million years old – evolutionary history of our family Hominidae, and it is obviously the species for which we have the richest fossil record.

Although it was actually not the first time ancient *Homo sapiens* were found, the discovery of fossil human bones in Abri Cro-Magnon in Les Eyzies-de-Tayac (Dordogne, France; Lartet 1868) was a major milestone in the history of two emerging disciplines at the time: prehistory and palaeoanthropology. Indeed, the human skeletal remains from Cro-Magnon corresponding to at least four adult individuals were described as belonging to *Homo sapiens*, but with marked differences in morphology and size with people living in this region of Europe in recent times. Few years after the publication of *On the Origin of Species* by Darwin in 1859, the Cro-Magnon findings pointed for the first time at a possibly very long (pre)history of our species *Homo sapiens*. Since then, several fossils recognized as belonging to early *H. sapiens* have been discovered, at considerably older dates than the c. 30,000-year-old Cro-Magnon individuals. The oldest fossils currently described as “fully *H. sapiens*” correspond to two individuals (Omo 1 and Omo 2) recovered from geological layers dated to c. 200,000 years ago at the Omo Kibish site, near the Omo River in Ethiopia (McDougall et al. 2005). Interestingly, the morphologies of those two individuals show great differences, documenting a variation that is larger than what is found inside a single population of present-day *H. sapiens*. While Omo 1 presents a very derived, “anatomically modern,” cranial and postcranial skeleton, the skull of Omo 2 retains much more “primitive-looking” features. More recently, new discoveries and new studies of fossils from the site of Jebel Irhoud (present-day Morocco) indicate that “*Homo sapiens*-like” hominins were present in Northern Africa by at least 300,000 years ago (Hublin et al. 2017). Although the Jebel Irhoud fossils present few cranial and endocranial primitive-looking features, their facial, mandibular, and dental morphology align them with AMH, at a time period that is more than 100,000 years earlier than that of the Omo Kibish fossils. Despite a fossil record for African hominins that is still very scanty between c. 500,000 and 200,000 years ago, the Jebel Irhoud findings indicate that the origin of *H. sapiens* might have been more

gradual than what was thought before. It possibly involved various human groups present on the whole African continent and mosaic evolutionary processes with the appearance of *H. sapiens* skeletal features at different times, during a rather long period of time.

### How to Recognize a Fossil *Homo sapiens*?

These early African fossils illustrate perfectly the difficulties related to the definition of *H. sapiens* in an evolutionary perspective, i.e., including fossil specimens and thus based on features which are preserved and observable on fossil assemblages. If there are a large number of skeletal features which distinguish *H. sapiens* from other living great apes, it is much more difficult to pinpoint the features which are actually differentiating *H. sapiens* from other penecontemporaneous species of the genus *Homo*. *H. neanderthalensis* is obviously the best-known extinct hominin since it is documented by numerous fossil assemblages, representing dozens of different individuals and absolutely all skeletal elements. For many years, palaeoanthropologists were able to list series of features which are different between *H. neanderthalensis* and *H. sapiens*, often considering that this list was de facto defining the latter species. However, this was considerably revised, especially after the discovery near Lake Turkana in Kenya of the c. 1.6 million-year-old Nariokotome skeleton (the “Turkana boy”) in 1984. This skeleton of an adolescent assigned to *H. ergaster* (or *H. erectus* for some authors) presents most of the skeletal features which were listed as characteristic of *H. sapiens*, indicating that it is in fact the skeletal anatomy of *H. neanderthalensis* which is highly derived, and not necessarily that of *H. sapiens*. Taking into account its present-day variation and the most recent fossil discoveries, *H. sapiens* can be defined from the following skeletal features: a *mentum osseum* (i.e., a “true bony chin”), a large and globular braincase, a short face, a flexed basicranium, small teeth with a simplified (external and internal) morphology, and few postcranial features related to the shape of the pelvis and femur (e.g., Stringer 2016). The main

problem with those features is that, once they are quantified and analyzed for the genus *Homo*, most of them show a large intra- and inter-specific variation, which makes the recognition of a “threshold” for *H. sapiens* very difficult (or arbitrary). The qualification of “*Homo sapiens*-like” hominins for the Jebel Irhoud fossils is a good illustration of this conundrum. Because the shape of their braincase is less globular than what is documented in living and fossil *H. sapiens*, some scholars consider that it is not possible to assign them to *H. sapiens s.s.*, but others consider they present “enough” derived features of *H. sapiens* to be actually considered as such.

### Hypotheses on the Origin of *Homo sapiens*

The question of the origin (place and time) of our species has always been a major topic of interest, and it was the subject of a particularly vivid debate for more than 50 years (from the 1940s to the 1990s). Based on fossil and archaeological evidence, two main evolutionary hypotheses were proposed. The first one, developed after the pioneer work of F. Weidenreich in the 1930s and 1940s, is traditionally known as the “multi-regional model.” According to this hypothesis, hominin evolution was marked by a single major Out of Africa event, corresponding to the dispersal of *Homo erectus* into various regions of the Old World (e.g., East and Southeast Asia, Europe). This major dispersal event was followed by continuous processes of regional evolution and frequent episodes of interbreeding between populations living in neighboring regions. Combined together throughout time, those processes led to the gradual emergence of *H. sapiens* more or less simultaneously in different regions of the Old World. This hypothesis was challenged by an alternative model called the “Out of Africa” hypothesis. According to this hypothesis, the origin of the species *H. sapiens* is quite recent and African only, that is, *H. sapiens* went out of Africa from where the species originates and dispersed into Eurasia, replacing other species of the genus *Homo* which were still possibly present in those regions (like *H. neanderthalensis* in Europe, late *H. erectus* in Indonesia, etc.). In the 1990s and

early 2000s, discoveries of fossils in Africa and genetics of living human populations brought an almost unanimous support to the “Out of Africa” hypothesis. Analysis of present-day human mitochondrial DNA (“mtDNA”), Y chromosome, and nuclear DNA allowed us to trace back the origin of all living *H. sapiens* to regions situated in Eastern or Southern Africa and a major Out of Africa event dated to c. 60,000–80,000 years ago (e.g., Quintana-Murci et al. 1999; Underhill et al. 2000).

### The Onset of a Specific *Homo sapiens* “Modern Behavior”?

Archaeologically, the behavioral traits, cultural diversity, and cognitive changes which accompanied the appearance and evolution of *H. sapiens* are also difficult to assess. Nevertheless, for the last three decades, besides the results of paleoanthropological and genetic studies, the many discoveries of cultural assemblages (material remains) allowed us to better characterize the emergence of our species from a cultural point of view, defining new theoretical approaches (together with new methodological developments). These studies resulted in the recognition of a “modern behavioral package,” which would characterize the uniqueness of AMH. Several models have been proposed to contextualize this (r)evolution.

One of the first models was arguing for a relatively late development of modern behavior during the Late Upper Pleistocene. Thus, even if “modern morphological features” were already present in the Early Upper Pleistocene, “modern behaviors” would have developed later, between 50,000 and 40,000 years ago, in relation with cognitive changes in the human brain, which allowed the expansion of the Upper Paleolithic in Europe (Klein 1995).

Pointing out the eurocentrism approach of this paradigm and the push back in time of the AMH roots (i.e., new ages of Omo or Jebel Irhoud fossils) as well as those of some important technical shifts in Africa (e.g., blades, retouched point, Levallois debitage methods) from ~300,000 years ago – and thus predating the first AMH – fostered new models. One of it argues for a gradual

and mosaic emergence of new major technical and socioeconomical features, appearing and disappearing at different times and places, from the end of the Middle Pleistocene (Foley and Lahr 1997; McBrearty and Brooks 2000). Technical evolution toward a more elaborated and diverse toolkit than before and hafting technology is linked to the development of complex hunting strategies. The invention of projectile weaponries with retouched point manufacture, recurrent blade production, diminution size of the weapons, and hafting proceeds appears thus to have not only been a technical evolution but also a major behavioral and social shift, facilitating territory management and population movement/mobility and demography and forcing new structured social organization. These societal organization enhancement would then have been accelerated during Later Stone Age in Africa from mid-Upper Pleistocene (i.e., from c. 70,000 to 50,000 years ago; Villa et al. 2012) and a trend to an important weaponry diminution in size and the microlithization of tools (bladelet production, backed pieces, and geometrics).

Besides these major developments, other structuring traits of *Homo sapiens* highlighting a complex social organization are correlated to the diversification and intensification of symbolic behaviors. Complex behaviors linked to non-direct utilitarian production and related to the expression of singular and conceptual relationship with environment, such as rock paintings, personal ornamentation, or even mortuary practices, are not born with modern humans. Many references show that this kind of practices predates the emergence of AMH, including Neanderthals' expansion. Nevertheless, during the last 100,000 years ago, new symbolic practices are directly related to the development of *Homo sapiens*. These new activities can be seen as a kind of "modern signature," whose Upper Paleolithic from c. 40,000 years ago and its artistic expression explosion are the most representative. Nevertheless, even before, they appear and develop more or less sporadically in Africa and can be attested by the production of engravings on pigment pieces and ostrich eggshell or the manufacture of eggshell personal ornaments. Finally,

as other innovations, those related to symbolic behavior of *H. sapiens* took their singularity in their diversity and intensification through time.

In this sense, the way members of our species take care of their dead is symptomatic, even if mortuary practices are not a modern humans' apnage, nor a "specific" innovation. Indeed, examples of special attention to the deceased predate *H. sapiens*, as shown by human remains recovered from the sites of Bodo (African *H. heidelbergensis* or *H. rhodesiensis*) or Sima de los Huesos (*H. heidelbergensis*), for instance. More recently in the chronology, Neanderthals had similar primary burial practices with *H. sapiens*, whether they had independent or inherited origins. Nevertheless, *H. sapiens*' prehistoric societies also show highly diverse and variable mortuary/funerary practices, resulting in many different practices that can be seen nowadays.

In fine, more than a specific and linear "modern" behavioral drift, all these gradual modifications provide a mosaic image of the sociocultural characteristics of *H. sapiens*. The variety and variability of these traits may thus be one of the trace elements of our species roots (Shea 2011).

All the more so as because large part of these major changes (technical innovations, complex social structuration, or symbolic behavioral traits), which question the emergence of a specific modern cognition, are challenged by the presence of similar cultural advancements among penecontemporaneous Neanderthal populations. These common features shared by different human species at the same time highlight the difficulty that we, present-day *H. sapiens*, encounter to define, identify, and conceptualize our specific (or not) and original (or not) cultural mechanisms, which drove the success of the "conquest" of the all world by our species.

## ***Homo sapiens* at the "Conquest" of Planet Earth**

### **Leave (and Not Leave) Africa: *H. sapiens*' Dispersals Throughout Africa**

The history of the Out of Africa and dispersals of *H. sapiens* can sometimes seem misleading. One

must not imagine that, as soon as the species was born in Africa, all of its members left it completely. Since the time of its origin until today, the history of *H. sapiens* is largely African. Our cradle is African, although its precise location remains the object of debates. In the present state of our knowledge, the earliest fossils of *H. sapiens* have been found in Eastern and Northern Africa, and they are dated to around 200,000 years ago and 300,000 years ago, respectively (see section “[From Cro-Magnon to Omo Kibish: The Earliest Fossil Evidences for Homo sapiens](#)”). Genetics of living populations alternatively pinpoint Eastern Africa or Southern Africa as the possible regions of origin for all living humans. Surprisingly, the processes involved in and the timing of the early dispersals of *H. sapiens* inside Africa are still rather poorly documented and understood. Between 120,000 and 100,000 years ago, *H. sapiens* was present in Southern Africa, as shown by discoveries made in several sites, such as Klasies River Cave, Border Cave, and Blombos Cave, for instance. The earliest *H. sapiens* fossils known to date from Central Africa were found in the site of Ishango (Democratic Republic of Congo), and they are dated to only 20,000–25,000 years ago (Crevecoeur et al. 2016). However, as for early hominins, the fossil record of Western and Central Africa for ancient *H. sapiens* is very poor, possibly due to unsuitable conditions for conservation and fossilization of skeletal remains.

### A Series of Aborted Out of Africa Events?

The first Out of Africa events of *H. sapiens* are documented by data and results derived from palaeoanthropology and genetics which are a priori contradictory. For years, the oldest fossil *H. sapiens* known outside Africa were those discovered in the 1920s–1930s in the Levantine sites of Skhul and Qafzeh (present-day Israel) and dated to between 120,000 and 90,000 years ago. More recently, two series of important discoveries related to earlier dispersals of *H. sapiens* out of Africa were announced. Fossil teeth of *H. sapiens*’ morphology and dated to between 80,000 and 120,000 years ago have been discovered in 2011–2013 in Fuyan Cave (present-day China), indicating an early presence of *H. sapiens*

far away from the African cradle (Liu et al. 2015). And a fragmentary maxilla with teeth discovered in Misliya Cave (Israel) and dated to at least 177,000 years ago may suggest that *H. sapiens* was already present outside Africa long time before the time period documented in Skhul and Qafzeh (Hershkovitz et al. 2018). All these fossils present morphological attributes that leave few doubts about the fact that they belong to the species *H. sapiens*, but genetics indicate that the Out of Africa event which is at the origin of all humans currently living on the Eurasian, Australian, and American continents occurred later, between 60,000 and 80,000 years ago (see section “[Hypotheses on the Origin of Homo sapiens](#)”). The most parsimonious explanation for those apparently discordant results is that these early dates may correspond to one or several “aborted” Out of Africa events. Human groups involved in those early dispersals may have disappeared without leaving any descendants in present-day human populations.

### New Territories, Encounters, and Interbreeding

During the chronological windows during which *H. sapiens* expanded out of Africa, it was not the only species of the genus *Homo* living on the planet. To date, at least two – probably three – other different human species have been recognized in the fossils recovered from Eurasia. The most famous and best documented of these species is *H. neanderthalensis*, whose first fossil remains were discovered as early as 1829 (Engis 2 child, though its actual recognition as a Neanderthal occurred several years later). There is a very rich fossil record for *H. neanderthalensis*, which indicates that the species lived between more than 350,000 years ago and c. 40,000 years ago. Neanderthals occupied a geographical area covering Europe, the Levant, and Central Asia, with its easternmost extension known to date in the Altai Mountains (Siberia, present-day Russia). A long-standing question in prehistory and palaeoanthropology is as follows: “Did *H. sapiens* meet with *H. neanderthalensis* after its Out of Africa? And if so, what happened?” While there is still very little solid archaeological

and fossil data to address those two questions, ancient DNA (i.e., extracted from hominin fossils) gave major results. The first successful sequencing of ancient hominin DNA was obtained from the mtDNA of *H. neanderthalensis* skeletal remains in the 1990s, then rapidly increasing in numbers during the 2000s (see Nielsen et al. 2017). The results of the first studies showed that *H. sapiens* and Neanderthals differ significantly in their mtDNA. However, their nuclear DNA, which was first successfully sequenced in 2010 (Green et al. 2010), gave quite different results. Nuclear DNA indicates that *H. sapiens* and *H. neanderthalensis* had a long shared evolutionary history with a rather recent date of divergence (various estimations between c. 800,000 and 400,000 years ago), which is coherent with what is known from the fossil records. But these studies show that several independent events of interbreeding between the two groups occurred in Eurasia, well after their initial divergence. Because all present-day “non-African” humans carry a very small percentage (1.8–2.6%) of “Neanderthal DNA” and not Africans, it seems that those interbreeding events occurred in Eurasia only, after the main *H. sapiens*’ Out of Africa. In 2010, while attempting to sequence the DNA of a fragmentary hand phalanx from Denisova Cave (Altai Mountains, present-day Russia) which was supposed to be that of a Neanderthal, Krause and colleagues (2010) obtained a mtDNA sequence which was close to but significantly different from both *H. sapiens* and *H. neanderthalensis*. Several other DNA sequences have been obtained from additional fossils (teeth) since 2010, confirming that a previously unknown hominin was indeed living in Denisova Cave between c. 50,000 and 30,000 years ago. Because the fossil evidence is still too scarce for a proper morphological description of this new hominin, no new species name has been published for them yet (it is not allowed to publish a new species based on DNA sequences only), and they are still called “Denisovans.” Surprising also with the sequencing of those still rather “mysterious” hominins is the indication that they also interbred with *H. sapiens*. Small percentages of “Denisovan DNA” are found in

some present-day human populations, mainly from East Asia and Oceania, but the exact timing and geographical location of those interbreeding events between *H. sapiens* and “Denisovans” are still largely unknown.

### Asia, Australia, Europe, America, and the Pacific

The hypothesis which is currently the most widely accepted for the earliest dispersal of *H. sapiens* into Eurasia is that, after going out of Africa c. 80,000–60,000 years ago, they first went east, following a southern coastal route along the Indian Ocean. The archaeological evidence is still relatively scarce (and palaeoanthropological evidence virtually absent) to understand the details of their expansion in South Asia, but they probably reached Southeast Asia and Australia quite quickly, where they settled at least 60,000 years ago (Clarkson et al. 2017). The settlement of Australia is considered as an important milestone in the prehistory of *H. sapiens*’ dispersal because it implied sea-crossings, thus some sort of early navigation. However, *H. sapiens* was not the first hominin to cross the sea in island Southeast Asia. Indeed, the discovery of fossils assigned to the species *Homo floresiensis* in 2004 (Brown et al. 2004) indicates the presence in the cave of Liang Bua on Flores Island (present-day Eastern Indonesia) of these very small-bodied hominins from c. 100,000 to c. 60,000 years ago. Additional hominin fossils discovered in another site of Flores Island (open air site of Mata Menge) in layers dated c. 700,000 years ago demonstrate that hominins possibly related to *H. erectus* were able to cross the sea long time before *H. sapiens* and that these hominins subsequently experienced the effects of insular endemism (“insular dwarfing”). It is currently not known if *H. sapiens* and *H. floresiensis* actually met, but the chronologies of their presence in the region potentially overlap, and suggestions have even been made of a possible correlation between the extinction of *H. floresiensis* with the arrival of *H. sapiens*. Up to now, it is not possible to know if interbreeding events occurred because sequencing of *H. floresiensis* DNA has been unsuccessful so far.

The chronology of the earliest presences of *H. sapiens* in Asia indicates its populations extended to the north, probably from Southeast Asia to Eastern and Central Asia. However, this hypothesis might need to be revised if the early dates for *H. sapiens* in China are confirmed and if they are related to the same global dispersal events (and not one of the possible aborted Out of Africa events; see section “[A Series of Aborted Out of Africa Events?](#)”).

Europe, which was occupied by *H. neanderthalensis* until c. 30,000 years ago, was one of the last large areas of Eurasia to be settled by *H. sapiens*. The timing and process of the Neanderthal demise, and their replacement by AMH between c. 45,000 and 30,000 years ago is still debated. The early phases of Upper Paleolithic, assumed to highlight the very first arrival of AMH groups in Europe, are diagnosed from the assessment of technical features, particularly based on blade, bladelet, and bone tool production. They have been viewed as transitional and regional facies representing AMH migration from Central Asia and Levant. Nevertheless, human fossils are rare, and therefore pinpointing the authorship of these productions is sometimes challenging and the focus of extensive discussion. Two fragmentary fossils from Western Europe (Kent’s Cavern in the UK and Grotta del Cavallo in Italy) gave dates at c. 40,000 years ago, but their exact age and/or attribution to *H. sapiens* remains to be discussed. The earliest and best documented individuals securely attributed to *H. sapiens* are from Eastern Europe, like the individuals from Peștera cu Oase dated to 37,000–42,000 years ago. It roughly corresponds to the timing of the onset of Upper Paleolithic features in Europe, which frames the progressive replacement of the Neanderthal Middle Paleolithic populations. Interestingly, DNA analysis of one of the individuals from Oase showed that 6–9% of its genome is derived from Neanderthal (Fu et al. 2015; and see section “[New Territories, Encounters, and Interbreeding](#)”).

The timing of the first arrivals and the processes of dispersal of *H. sapiens* in America have been debated for a very long time. While

archaeological findings attributed to *H. sapiens* dated to c. 30,000 years ago have been reported from South America, it is currently accepted that *H. sapiens* arrived at least 15,000 years ago (Goebel et al. 2008). By that time, *H. sapiens* was present on most of the planet, with the exception of the northernmost latitudes and of the hundreds of islands of remote Oceania Pacific, which were settled later on by skilled long-distance navigators (Kirch 2017).

## Conclusion

At around 60,000 years ago, *Homo sapiens* was only one of the at least three and possibly four different species of the genus *Homo* which were living on earth. It is the only one which survived until today. *Homo sapiens* has a long evolutionary history, which started several hundred thousand years ago, somewhere in Africa. Its abilities led our species to inhabit all regions of the world, including some of the harshest ones, surpassing cyclic global environmental changes. Such challenges allowed our species to achieve exceptional levels of technological skills development, resulting today in a large cultural and biological diversity.

Marked by a complex link between biological and cultural adaptations, the evolution of *H. sapiens* is singular. This link seems to have strengthened since the onset of the Neolithic c. 12,000 years ago, which appears to be a “revolution” in terms of relationships between humans and nature. From this period, the impact of human activities on the environment changed the balance of natural selection. This new tendency toward an increased *anthropization* of landscapes finally resulted in a new situation where one species – *H. sapiens* – can influence and deeply affect climate changes and biodiversity (“sixth extinction” issues). *H. sapiens* can also, at least to some extent, guide its own evolution, modifying its biology through cultural choices. In this sense, *H. sapiens* is becoming the first biocultural group in the history of life to endorse major responsibilities in global future, including its own.

## Homogametic

Manohar Lal Yadav and Bhagyalaxmi Mohapatra  
Cytogenetics Laboratory, Department of Zoology,  
Institute of Science, Banaras Hindu University,  
Varanasi, UP, India

## Synonyms

### Homogamety

## Definition

“Organisms or individuals producing one kind of gametes.”

## Introduction

The term **homogametic** is often used to define an organism or individual producing all the gametes of same type. The homogametic individuals possess matching pair of sex chromosomes in contrast to **heterogametic** individuals which carry sex chromosomes of different types. Because of the presence of identical sex chromosomes, the homogametic individuals produce one type of gametes carrying identical sex chromosome whereas heterogametic organisms produce two different types of gamete with distinct sex chromosomes (Graves 2006; Namekawa and Lee 2009). For example, in human, females carrying two “X” chromosomes (i.e., sex chromosomes in female) produce only one type of gametes (X-bearing) and are homogametic while males possessing both “X” and “Y” chromosomes (i.e., sex chromosome in male) are heterogametic producing half of the gametes having X- chromosome while the other half are Y- bearing (Graves 2006; Namekawa and Lee 2009).

Homogamety or heterogamety is not restricted to one specific sex. Both the phenomena could be seen in both the sexes. Although in most cases males are heterogametic and females are homogametic, in certain other species males are homogametic while females are heterogametic. Some examples of homogametic male and homogametic females are given below.

## Homogametic Male

Examples of homogametic males are represented by most of the avian species, moths, and few species of fishes. Here, males retain two identical sex chromosomes that are designated as “ZZ” while female hold either two different sex chromosomes (ZW) or only one sex chromosome (Z0). This can be further divided into two types:

- (a) **Z0-ZZ Type:** In this case, the male individual possesses two identical sex chromosomes

“ZZ” and therefore, produces all the gametes of same type with “Z” sex chromosome. However, females are heterogametic and produce 50% gametes with “Z” chromosome while other 50% gametes without “Z” chromosome. This is called as **Z0-ZZ** type of sex determination. The sex of organism is determined by the gametes produced by female organism. If male gamete bearing “Z” chromosome fuses with female gamete carrying “Z” chromosome, the progeny will be a male while fusion of male gamete (Z) to female gamete carrying “0” sex chromosome resulted in a female organism, e.g., butterflies and moths (Kaiser and Bachtrog 2010)

- (b) **ZW-ZZ Type:** Here, the male organism produces all the gametes with “Z” sex chromosome. However, unlike “Z0-ZZ” mechanism, female organism of “ZW-ZZ” arrangement produces half of the gametes with “Z” chromosome while second half of the gametes with “W” chromosome. Like “Z0-ZZ” system, determination of sex is decided by the gametes derived from female germ cells (Schartl 2004; Graves 2009). The ZZ-ZW system of sex determination has been reported in several reptiles and birds.

### Homogametic Female

Here, female organism possesses two identical sex chromosomes and therefore, produces all the gametes of same type. This can also be divided into two types.

- (a) **XX-XY Type:** This type of sex determination is present in mammals including humans, plants, and many insect species like *Drosophila*, etc. The homogametic females produce only one type of gamete all having “X” chromosome. However, heterogametic males produce 50% gametes with “X” chromosome while the rest 50% with “Y” chromosome. Mostly, sex is decided by the male gametes, although in some species like *Drosophila*, it is the ratio of autosomes and sex chromosome which determine the sex of an individual (Waters et al. 2007; Ellegren 2011).
- (b) **XX-X0 Type:** Here, female individual is homogametic and produces only one type of

gamete. The male individual produces half of gametes with “X” chromosome and rest half gametes without “X” sex chromosome, i.e., (0). The sex is decided by the gametes generated by the heterogametic individual, for example, grasshopper, cockroach and cricket (Kaiser and Bachtrog 2010).

Like animals, homogamety as well as heterogamety has also been reported in plants. In plants also, homogametic sex produces only one type of gametes while heterogametic sex produces two type of gametes, i.e., male determining gametes and female determining gametes in equal proportions. Several species of angiosperms, gymnosperms, and bryophytes carry heteromorphic sex chromosomes in one sex and identical sex chromosomes in another sex, similar to XY/male and XX/female system. Identification of homogamety or heterogamety in plants is very complex and can be determined by different ways including identification of heteromorphic sex chromosomes, crossing between dioecious (male and female flowers occur on different individuals) and bisexual, i.e., male and female flowers occur on the same plants species, self-fertilization (or intercrossing) of bisexual individuals from normally dioecious or sub-dioecious species, etc. *Melandrium* and *Fragaria* represent the male and female heterogamety, respectively. The complexity of determination of homogamety and heterogamety in plants occur due to presence of dioecious, monoecious (i.e., stamens and pistils are restricted to separate flowers on the same plant), and hermaphroditic (male and female are found in the same flower) sexes in plants as well as absence of morphologically distinct sex chromosomes among two sexes (Westergaard 1958; Charlesworth 2016).

### Evolution of Sex Chromosomes: Homogamety and Heterogamety

Since, homogamety or heterogamety of an organism is dependent upon the presence or absence of distinct sex chromosomes, the evolution of sex chromosomes is very important to understand these two phenomena. Sex chromosomes evolved independently from the autosomes under certain

evolutionary forces which ceased the recombination and eventually led to the formation of discrete chromosome types. The evolution of two distinct sex chromosomes such as “X” and “Y” chromosomes leads to heterogamety. Further, partial or complete inhibition of recombination or genetic exchange between sex chromosomes is associated with the lack of genetic homology between the relevant regions of “X” and “Y” chromosomes which eventually help to retain the heteromorphic nature of sex chromosomes (Charlesworth 1991; Ellegren 2011).

Evolution of sex chromosomes in plant has evolved recently and independently in different taxonomical groups. Some plants may be in the early stage of evolving separate sexes, and therefore these plants lack sex chromosome. Some plants seem to have small nonrecombining regions, i.e., proto-sex chromosomes; however, a few species possess cytologically detectable heteromorphic sex chromosomes with large non-recombining regions (Charlesworth 2016).

## Synonyms

[Homological](#); [Homologous](#)

## Definition

Homology is the concept of physiological, morphological, or behavioral features in an organism that arise from common evolutionary ancestry.

## Introduction

When organisms diverge from each other in evolution, the resulting specialized traits can appear (and function) vastly different. However, upon closer inspection, evolutionary links often remain in the related species. A well-studied example of this can be observed in Fig. 1. The figure shows the similarities in structure development between a human hand and that of a bat wing. While the general bone positions and number are comparable, their functions are very different. Through time, the originally similar bat and human bones have evolved to serve unique purposes. Although it is probably most well-known for relating the physical characteristics of animals together, homology has been an important concept in exploring fields like genetics, learning, and behavior. By observing traits in different

**Homology, Fig. 1** A comparative image showing the homologous bone structure of two mammals, a bat and human, each serving very different functions

organisms with common ancestors, conclusions can be made about the evolution, function, and interaction of those traits in their homologous counterparts. Homology is not to be confused with the similar term analogy; homologous features are of the same origin and may have modified purposes, while analogous features come from different origins but serve the same purpose.

## Homology in Physical Features

### Homology and Evolution

Natural selection acts on populations over time to optimize physiological function and morphological characteristics necessary for survival and reproduction in their environment. This process can be observed in the physical structure of animal bodies, such as the musculoskeletal system. Because bones can be preserved through time, they can be used to identify the history of evolutionary pathways in an organism. Even with changes to embryonic developmental mechanisms, homologous features in skeletons can still remain (Hirasawa and Kuratani 2015).

### Neurological Homology

Homology is also useful in understanding the structure of an organism's nervous system and can lead to inferences about neural function, sensory systems, learning and memory, and cognitive ability. In mammals, stimulating homologous regions of the brain has been shown to create similar emotional responses across species. More than seven types of homologous expressive reactions have been identified this way (Panksepp 2011).

### Homologous Genes

Advances in genome mapping have now allowed researchers to quantify the genetic makeup of animals and identify homologous genes. This ability is useful in modeling common genetic ancestry across multiple species, such as fruit flies (*Drosophila melanogaster*). Different behaviors or symptoms due to genetic expression of homologs in *Drosophila* can be compared directly to genetic expressions in humans, but with

much faster time scales and controlled settings (Chakraborty et al. 2011).

## Homology in Cognition/Learning and Behavior

### Human-Animal Behavioral Homology

Aspects of homology can also be found in learning and behavioral characteristics. Because animals can have homologous nervous systems, the behavioral responses and learning abilities of those systems can also be homologous. In humans, these cognitive similarities are present during the start of development (Platt and Spelke 2009). The similarities in biological evolution allow for research into human cognitive disorders by observing animal models with homologous conditions (Geyer and Markou 2000). Dogs, in particular, have been presented as effective models for assessing psychiatric conditions in people. If the disorders found in canines have a homologous counterpart in humans, research concerning treatment for one species can further that of the other (Overall 2000).

### Uniform Homologous Behavior

All mammals have identifiable behavioral homologies that represent uniform cognitive traits which aid in survival and fitness (Kiley-Worthington 2017). The presence of social learning (learning influenced by other individuals) has been found in a wide range of animals, including insects (e.g., *Drosophila*) and is argued to stem from homology and homologous characters. The evolutionary value of such similar behavior systems should not be overlooked (Collet 2012).

## Conclusion

When employed properly, studying homology gives valuable insight to many aspects of animal biology and behavior. By studying the evolutionary history of these shared characteristics, researchers are coming to new and exciting

conclusions about connections that might have been impossible to discover previously. Between the similarities in body design to the corresponding cognitive and behavioral traits, homology is a vital part of understanding animal biology and behavior.

## Homology Directed Repair

### ► Targeted Mutation

## Homoplasy

Priyanka Verma and Kiran Singh  
Department of Molecular and Human Genetics,  
Banaras Hindu University, Varanasi, India

### Definition

Homoplasy can be defined as the similarity between taxa which is due to independent evolutionary change. In simple terms, similarity in sequence or structure that cannot be derived from common descent.

### Homoplasy

Homoplasy is an interesting and infrequent incidence of evolution. This term was given by Lankester in 1870. Homoplasy and homology are very confusing terms and a thin line difference lies between these terminologies. Homology is the similarity of a trait due to shared ancestry and offers valid phylogenetic signal (Hall 2007). However, homoplasy is the similarity of a trait that can be due to evolutionary convergence, parallelism, or character-state reversals and adds an evolutionary noise. If not properly accommodated, it jeopardizes the phylogenetic tree (Wake et al. 2011; Robinson et al. 2008).

For example, the wings of birds and bats are an example of both homology and homoplasy. The bones within the wings are an example of

homology because internal structure of bones such as breast bone, large upper arm bone, two forearm bones, and hand bone share common ancestry group. However, the wings themselves are an example of homoplasy because bats and birds evolved their wings to fill a niche and survive in their respective environments.

Homoplastic traits are derived from three evolutionary mechanisms (Wake et al. 2011, Wake 2015, Campbell and Hodos 1970):

- (a) **Convergence:** The homoplastic trait is not present in the common ancestor. The structures originated by convergence are called analogy. This kind of homoplastic traits has evolved independently through different development pathways. An example is the wings of insects and birds.
- (b) **Parallelism:** Ancestral condition of a variable trait is present in common ancestor but derived trait has evolved independently through similar development pathways, e.g., development of four chambered heart in birds and mammals (Abouheif 2008).
- (c) **Reversals:** Reversals are instances of homoplasy in which a character appears, subsequently disappears, and later reappears along the descendants in one lineage.

Statistically, amount of homoplastic trait present in a cladistic tree can be measured by three methods:

- (a) **Consistency index:** It is introduced by Kluge and Farris (1969) as a measure of a homoplastic character, which has been widely known. It is calculated as the minimum number of changes in the cladogram divided by the actual number of changes needed for the cladogram. It occupies a range from 0 to 1. A low consistency index (less than 0.5) indicates that much homoplastic trait and high consistency index ( $\geq 1$ ) indicates no homoplastic trait present in the cladogram.
- (b) **Retention index:** It can be measured as the proportion of taxa whose states are not homoplastic (i.e., do not evolve more than once). It also measures synapomorphies character of a clade (Archie 1996; Farris 1989).

- (c) **Homoplasy excess ratio:** It is the best way to measure homoplastic traits and widely utilized. It is calculated as the amount of homoplasy observed on a tree relative to the maximum amount of homoplasy (Archie 1989).

## Homosexual

Rachel Schepke and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

[Homosexual ideology](#); [Homosexuality](#); [Homosexuals](#)

## Definitions

Homosexual *orientation* refers to a set of traits and preferences whereby an organism is exclusively sexually attracted to and interested in same-sex individuals. Homosexual *behaviors* refer to sexual behaviors with same-sex individuals.

## Introduction

Homosexual *behaviors* occur in most sexually reproducing species, whereas homosexual *orientation* (exclusive sexual interest in and preference for same-sex individuals) may be unique to humans (Baker and Bellis 2014/1995; Kirkpatrick 2000). Individuals of many species display homosexual behaviors to gain acceptance, solidify a social bond, or experience pleasure. Males that display homosexual behaviors may participate in anal sex, oral sex, or mutual masturbation with males, and females that display homosexual behaviors may participate in mounting, oral sex, and mutual masturbation with females (Baker and Bellis 2014/1995; Sommer and Vasey 2006; Vasey 2004). In many species, males do not engage in homosexual behaviors after reaching reproductive age. Homosexual behaviors may be displayed by heterosexually, bisexually, and homosexually oriented individuals.

## How Homosexual Orientation Persists in the Population

There is evidence that homosexual orientation is heritable such that homosexual males and females carry genes that contribute to the development of homosexual orientation (Apostolou 2013; Baker and Bellis 2014/1995; Blanchard and Bogaert 1996; Iemmola and Ciani 2009; Kirkpatrick 2000). Bisexual individuals also may carry genes that contribute to the development of homosexual orientation. Thus, individuals that copulate with a homosexual or bisexual individual may transmit genes to offspring that contribute to the development of homosexual orientation.

Birth order accounts for some of the variation in male homosexuality in humans. Men with a greater number of older brothers are more likely to be homosexual (Apostolou 2013; Blanchard and Bogaert 1996; Ellis and Blachard 2001; Iemmola and Ciani 2009; Kirkpatrick 2000). The maternal immune hypothesis suggests that mothers produce higher rates of antibodies to testosterone during each subsequent male pregnancy. Later-born sons are more likely to become homosexual when the mother passes antibodies to testosterone to the fetus during pregnancy, which reduces the hormone's biological activity of the fetus (Ellis and Blachard 2001; Iemmola and Ciani 2009).

## Homosexual Evolved Psychology

Homosexual and heterosexual humans share an evolved psychology for sexual preferences, although they differ in the target of these preferences. Like heterosexual men, homosexual men prefer sexual variety, physical attractiveness, and youth (Ha et al. 2012; Valentova et al. 2017). Male preference for physical attractiveness evolved because attractive females are more likely to produce healthy offspring (Apostolou 2013; Ha et al. 2012). Male preference for youth evolved because younger women have greater reproductive value – they are able to birth more children in their remaining reproductive lifespan (Apostolou 2013; Ha et al. 2012). The preference for sexual variety

motivates heterosexual men to pursue copulation with multiple partners. Although homosexual men do not produce offspring by copulating with other men, homosexual men value traits in the target of their sexual desire that indicate higher reproductive value when displayed in women. Homosexual men likely have similar mate preferences to heterosexual men because they have sex-typical evolved psychology.

Homosexual women also have sex-typical preferences including the desire for higher status, resources, and investment (Ha et al. 2012; Valentova et al. 2017). These preferences evolved because women and their offspring benefit by securing resources and investment from a long-term partner. Higher status is associated with access to resources (Valentova et al. 2017). The similarities between heterosexual and homosexual mate preferences may reflect an evolutionary mismatch – the mate preferences that are advantageous for heterosexuals do not solve the same adaptive problems for homosexuals.

In humans, a long-term partner's real or suspected infidelity is the primary cause of jealousy. Men are more upset by a partner's sexual infidelity because paternity is threatened when his partner copulates with another man. Women are more upset by a partner's emotional infidelity because her partner may invest time, attention, and resources into another woman and her children. Jealousy among homosexual individuals is less clearly sex differentiated (Ha et al. 2012; Valentova et al. 2017).

## Costs and Benefits of Homosexual Behaviors

Homosexual behaviors are not uncommon in many species; they occur with greater prevalence compared to exclusive homosexual orientations and may be associated with social and reproductive benefits. Individuals of many species engage in homosexual behaviors to secure social acceptance and to achieve higher ranking within a group. For instance, female bonobos display mounting, genital licking, and mutual masturbation with higher-status females (Sommer and Vasey 2006; Vasey

2004). Females of several primate species may provide sexual favors to higher-status females as displays of kindness or cooperation and thereby secure social support and acceptance from female troop members.

Some mammals, vertebrates, reptiles, and birds may engage in pre-reproductive homosexual behaviors to gain experience in courtship (Baker and Bellis 2014/1995; Sommer and Vasey 2006; Vasey 2004). Males that engage in anal intercourse with other males may improve their mounting skills and learn how to interact sexually with a partner, including practicing submissive and dominant roles. Such practice may improve a male's mating success with females. Males that are accommodating to the female during copulation are more likely to stimulate female orgasms, which may facilitate sperm retention (Baker and Bellis 2014/1995). Females that engage in pre-reproductive homosexual behaviors benefit by improving their sexual skills, practicing sexual receptivity, and experiencing orgasms. In humans, females may experience orgasms more frequently or more reliably during sex with females than with males. Thus, females may learn to control and achieve orgasm with males as a consequence of practicing sexual acts with females (Baker and Bellis 2014/1995).

Exclusive homosexuality may be associated with benefits to genetically related individuals, in the form of kin care. One theory suggests that homosexual individuals can invest resources in kin members, given that they do not incur the costs of rearing their own children (Apostolou 2013; Kirkpatrick 2000). Investing resources in kin may contribute to inclusive fitness. However, the siblings of last-born homosexual sons may have attained more resources from their parents, thereby increasing their reproductive success without the help from the youngest brother. Also, homosexual individuals may allocate resources to same-sex partners, which decreases the amount of resources distributed to kin.

## Conclusion

Homosexual behaviors are more common than is exclusive homosexual orientation. The persistence

of homosexual orientation in populations is influenced by genes and birth order. Pre-reproductive homosexual interactions may prepare both sexes for copulation with individuals of the opposite sex and may improve mating success. Homosexual humans have sex-typical preferences. In humans and other primates, homosexual behaviors may facilitate social acceptance and bonding with same-sex group members.

## Synonyms

[Autozygosity](#)

## Definition

Homozygosity is the state of having two identical alleles or chromosomal segments of DNA in diploid organisms.

## Introduction

Living organisms use molecules of deoxyribonucleic acid (DNA), organized into colloid structures called chromosomes, to store the genetic material that they inherit from their parents. The way in which genetic traits are passed on between generations was first described by Gregor Mendel (1865), before anyone knew that DNA existed. Organisms that reproduce sexually have a defined number of chromosome pairs, with each pair member received from each parent. Throughout the length of each chromosome distinct units appear called genes, which carry the genetic instructions to make the main elements of any biological activity: the proteins. The somatic cells of diploid organisms, such as human, have two copies, or alleles, of every gene that are located in the same locus, or position, on homologous chromosomes. Although the locus of an individual gene on homologous chromosomes is the same and may code for a specific physical trait, or phenotype, that gene can exist in different forms, or alleles. When both parents deliver the same allele of a defined gene, the offspring is called homozygous for that gene. Gene alleles produce phenotypes that are either dominant or recessive. When an organism carries one dominant and one recessive allele for a given gene, the dominant allele expresses itself at the expense of the recessive allele, which is only expressed in homozygous background. The genetic governing the expression of most traits is very complex, because one trait might utilize more than one gene to make a defined character. For example, eye color is influenced by more than one gene, but it is well known that the alleles that give rise to blue (b) eye color are recessives, while the alleles for brown (B) eye color are dominants (Sturm and Frudakis 2004) (Fig. 1).

**Homozygosity,**

**Fig. 1** *Brown versus blue* eye color determination. Allele for *blue* eyes (b) is recessive. Allele for *brown* eyes (B) is dominant. An individual with *brown* eye color will have one of the following genotypes, BB or Bb. An individual with *blue* eye color will be homozygous for the *blue* allele (bb)

**Definition of Homozygosity**

Homozygosity is used to describe a state of holding identical alleles at one or more gene loci on homologous chromosomes segments. When these alleles are different, we talk about heterozygosity (Fig. 1). One of the major mechanisms that are linked to homozygosity is inbreeding, or mating between relatives, a phenomenon that occurs in many animal and plant species, including human. As a result, inbred individuals inherit the same chromosomal segments from both parents, who inherited them from a common ancestor, recently in the case of a cousin marriage. By this mechanism, the quantity of homozygosity increases, while the amount of heterozygosity decreases. Therefore, the recessive alleles that are hidden by the dominant alleles will be expressed by inbreeding (Alvarez et al. 2011) (Fig. 2). The excess of homozygosity is distinguished by calling it autozygosity to reflect the recent common origin of the alleles.

The identical genomic segments that are present in the human genome because of identical

alleles that are transmitted from parents to their offspring are called “run of homozygosity” (ROH) (Purfield et al. 2012). ROH might also concern multiple adjacent single nucleotide polymorphisms (SNPs) in the genome (Nothnagel et al. 2010). An abundance of ROHs was first demonstrated in European populations using short tandem repeat (DNA regions with short repeat units) markers (Broman and Weber 1999). With the increasing availability of high-density genome scan data, attention has intensified to discover whether a more reliable and accurate estimate of homozygosity might be derived on the basis of genomic marker data. Currently, ROH might be statistically measured up to 1.5 Mega-base or more (McQuillan et al. 2008). The identification and characterization of ROH is important to ascertain inbreeding levels and the genetic relationship between individuals and populations (Ferencakovic et al. 2013). It is also critical to understand the occurrence of recessive disorders, mainly in human (Lencz et al. 2007) (See also the next paragraph).

**Homozygosity, Fig. 2** Typical pedigree of an autosomal-recessive disorder

H

## Consequences of Homozygosity

The genetic material of an individual is the target of many alterations, including SNPs, and deletions, insertions, or translocations of genomic material. The majority of genetic disorders are harmful if the two copies of a gene are affected, meaning that both gene alleles produce defective proteins that fail to operate correctly. In heterozygous genotypes, one copy of the gene is not affected and generates a functional protein; thus, these individuals are not affected and are considered just carriers, or might suffer from a milder form of the disease (Fig. 2). Because the genetic material is passed from parents to offspring, the consequence of genetic alterations in inbred individuals is an increase in the levels of homozygosity for deleterious recessive alleles, leading to a reduction in individual health. Charles Darwin was the first to report that inbreeding could lead to reduced fitness in plants (Darwin 1876). In human, the majority of cases of the rarest recessive genetic diseases occur as a result of consanguineous marriages due to homozygous expression of recessive genes inherited from their common ancestors. Recessive gene variants cause many deleterious genetic diseases such as cystic fibrosis, phenylketonuria, and Tay-Sachs disease.

A continuing goal of the human genome project is to determine the function of all human genes. Of particular interest is the identification of human phenotypes associated with the mutation of each gene. Although considerable progress has been made, the majority of genes causing complex and Mendelian disorders have yet to be identified.

## Synonyms

Cortex man; Cortical somatotopic map

## Definition

The primary sensory and motor cortical map representing the human body according to the area it covers for each body part.

## Introduction

In Latin, “homunculus” means the “little man” (Bear et al. 2007; Purves et al. 2014). It is the disfigured neural representation of the body in the primary somatosensory (post-central gyrus) and primary motor cerebral cortex (pre-central gyrus) (Barker et al. 2017; Snell 2010). It is a result of numerous trials and efforts made to localize the brain functions by mapping it, with the help of various electrical stimulation studies and neuroimaging techniques (Penfield and Boldrey 1937; Purves et al. 2014).

In the 1930s, Marshall observed that touching a specific part of an animal’s body results in an evoked potential in the contralateral cortex (Hudspeth et al. 2013). Evoked potentials are electric signals recorded from cells which represent their summed activity. This method was later used by others to map the brain (Hudspeth et al. 2013). In 1937, the mapping work of Wilder Penfield, Edwin Boldrey, and Theodore Rasmussen figured out two separate sensory and motor homunculi (Penfield and Boldrey 1937; Penfield and Rasmussen 1950).

In the late 1940s, Penfield stimulated the somatosensory cortex of patients and found that it produced sensations of touch in the contralateral hand or leg (Hudspeth et al. 2013; Nicholls et al. 2001). Thus, he concluded that sensation from the lower limbs is mediated by neurons located near the midline, whereas sensations from the upper body, hands and fingers, the face, and lips are mediated by neurons located laterally, on the post-central gyri (Barrett et al. 2009; Hudspeth et al. 2013; Snell 2010). This organization helps differentiate the types of epilepsy based on origin. Seizures originating in the primary motor cortex manifest in the form of the Jacksonian march, whereas those originating in the supplementary motor area (SMA) manifest as repetitive and complex movements (Barker et al. 2017). In 1950, Penfield and Rasmussen contrived a sensory and a motor homunculus, which differed in very few aspects (Penfield and Rasmussen 1950).

## Evidence

The sensory and motor pathways are topographically arranged in the cortex (Hudspeth et al. 2013;

Nicholls et al. 2001; Purves et al. 2014). Even though all parts of the body are represented somatotopically (Fig. 1), the area of cortex dedicated to a body part is not proportional to its mass. Rather, it correlates to the fineness of sensory discrimination (which consequently corresponds to a higher density of sensory receptors) and degree of motor control (Bear et al. 2007; Hudspeth et al. 2013). In other words, usage of the body part determines the size of cortical area devoted to it (Barrett et al. 2009). Therefore, homunculus is considered as an altered representation of the body (Fig. 1), having size of its body parts proportional to its concerned cortical area (Snell 2010). Therefore, the human homunculus

has an excessively enlarged face, tongue, hands, and fingers. In contrast, the trunk, proximal arms, and legs are shrunk (Purves et al. 2014).

In the somatosensory cortex, large areas are concerned with hands, lips, and tongue, as opposed to the elbow, upper legs, arms, and torso (Hudspeth et al. 2013; Purves et al. 2014). The output from the motor cortex is also arranged similarly with much more area devoted to muscles of fingers and those pertaining to speech (Hudspeth et al. 2013). These aspects translate into anomalies observed in the homunculi. This demonstrates that speaking, dexterity, and facial expression are critical and therefore require central circuitry to govern them (Purves et al. 2014).

H

**Homunculus, Fig. 1** The human homunculus is a distorted, neural, cortical representation of the body. All parts of the body are topographically arranged. Area of

cortex concerned with a particular body part is correlated with fineness of sensory input or control of motor output

**Homunculus, Fig. 2** Comparative cortical representation of the body in human, rabbit, and rat. The cortical representations of different parts of the body with respect to its actual physical size complement its importance to the species

The arrangement of components in the primary somatosensory and primary motor cortex follows a general rule of representation (Fig. 1), with few modifications. The sensation of eye movement is solely represented in the pre-central gyrus. Conjugate eye movements are represented further in front. Salivation is often a somatosensory response rather than a motor one (Penfield and Rasmussen 1950).

Functionally, the cerebral cortex is organized into cellular columns spanning the white and gray matter. The cells in each column comprise a computational module which has a specific function. The number of these computational columns is proportional to the area of cortex devoted to a body part (Barker et al. 2017; Hudspeth et al. 2013). Similarly, distorted depictions can be observed in other species (Fig. 2). In rats, whiskers are represented as disproportionately big because of its paramount role in sensing the environment (Bear et al. 2007). Raccoons have exaggerated paws, and the platypus overrepresents its bill (Purves et al. 2014). In rabbits, the face and snout have the largest representations because they are crucial in sensing the environment. Cortical representations of the parts of the body (Fig. 2) complement its importance to the species (Hudspeth et al. 2013; Purves et al. 2014).

## Conclusion

The sensorimotor homunculi represent functionality of different body parts on the contralateral side. A salient feature of the homunculi is its weird body proportions (Purves et al. 2014). The hands, fingers, mouth, and lips are disproportionately large when compared to the torso, arms, and legs. This indicates that a larger area of the cortex is dedicated to sensory input or motor output of organs which are exaggerated. Similar representations are seen in other species.

The “little man” has gained popularity since its inception because it is easy to assimilate in memory. It is a powerful tool that portrays the neural maps of the cortex at first glance. The homunculus, however, is an oversimplification (Nicholls et al. 2001). Many nuances of the neural maps, the intricate neural networks, and their projections are not described. How these projections process sensory information or conduct motor activity aren’t depicted in the homunculi (Nicholls et al. 2001).

## Honest Mimetic Signal

- [Müllerian Mimicry](#)

## Honest Signaling

Irena Petak  
Zagreb, Croatia

### Definition

Honest signaling conveys information that is a true indicator of the underlying quality of the sender and it is useful to the receiver.

## Introduction

In animal communication, information is transmitted from a sender (signaler) to a receiver, and the receiver acts upon the signal (McFarland 2006). Signals can be “honest” when giving reliable information or “dishonest” when the sender is sending out false information to a receiver (Laidre and Johnstone 2013).

## Evolution of Honest Signaling

According to signaling theory for a signal to be preserved in the population, the interaction should be beneficial for the sender and receiver. Furthermore, the honest signal should convey information that the receiver cannot obtain in another way. Honest signaling does not need to be perfectly informative, but it needs to be useful, so that certain behavioral responses to the signal are advantageous, in comparison with the behavior that would occur in absence of the signal. Therefore, honest signals in communication are given when both the sender and receiver benefit from the result (Laidre and Johnstone 2013).

Dishonest signaling doesn't have to suggest conscious deception, rather it has functional meanings in animal communication (Shettleworth 2010). Deceit takes place when the signaler can exploit the receiver in order to improve its fitness, and it is common in communication between species. Similarly, manipulation is when the receiver acquires information from the signaler contrary to his interests (McFarland 2006), and this may arise when sender and receiver have opposite interests (Laidre and Johnstone 2013). In evolutionary terms, dishonest signaling may persist if it doesn't harm recipient fitness or when it has a low frequency of occurrence (Laidre and Johnstone 2013).

Although animal communication is open to cheating, the receiver can choose whether or not to respond to a signal and therefore can impose honesty. Signals must be truthful indicators of underlying quality because the value of the signaled information rests on the degree to which it

enables the receiver to increase its fitness. If signals become unreliable, then the recipient will no longer respond to them (Laidre and Johnstone 2013).

Signals favored by natural selection are those that enhance an animal's probability of reproduction. Therefore, the honesty of a signaler's messages is guaranteed by their cost and that makes them evolutionarily stable. According to the Zahavi (1975) in mate choice and parental care, honest signaling develops because some signals are too costly for signalers to cheat, and that is termed "the handicap principle" (Laidre and Johnstone 2013) or "costly signaling" (Higham 2014). An individual without handicapping marker does not advertise its quality, so a potential mate cannot perceive it. That is to say, when the receiver answers only to costly signals, the sender's ability to pay the cost to define the evolution of communicative signals. Zahavi (1975) considered that signals such as loud calls or rich displays that require a lot of energy are reducing the fitness of the sender and so it can show its quality by its capability to survive in spite of the costs, i.e., handicap caused by signaling.

The handicap principle is generally acknowledged (Shettleworth 2010), but is still discussed (Higham 2014). However, the handicap principle is only one of several mechanisms that give possible explanations for the honesty in animal signaling, and honesty is possible without significant costs. For example, if signalers and recipients are related to each other or when they have negligible conflicting interest, then signals may be free of charge. Moreover, even when signalers and recipients have strong conflicts of interest, honesty is guaranteed if it requires lower cost than lying (Higham 2014; Laidre and Johnstone 2013).

In conclusion, signaling strategies may vary from cost-free cues to costly handicapping signals. Where any benefit for evolutionary fitness occurs, a cue may progress into to signal with a certain amount of exaggeration. Signals become exaggerated only when they start as weak cues of individual quality, but not when

they start as strong cues of quality (Biernaskie et al. 2018).

## Examples

The classic example of a costly honest signal that can't be explained by natural selection is the peacock feather tail. The tail has large feathers that require a lot of energy to grow, it is heavy, and it makes hard for peacocks to move around and to hide from predators. This signal is so costly that the signaler can hardly lie about its quality. However, this investment is effective because it improves the ability of females to choose mates of good quality (Shettleworth 2010; Zahavi 1975).

It is believed that Thompson's gazelles "stot" is an honest signal because it demonstrates gazelle's good body condition, stamina, and strength. Indeed, higher rate stotters appear to be better at running and escaping. This discourages the predators from attacking, and therefore the signal provides an advantage to both parties. The gazelle is less likely to be attacked, and the predator avoids a long, unproductive pursuit (Krebs and Davies 2006; Dawkins 2007).

Leal (1999) studied push-up display in lizard *Anolis cristatellus*, which is common in anoline social interactions. In the research, lizards were faced with a model of a natural predator, snake *Alsophis portoricensis*. The research confirmed that the number of push-ups that lizard performed toward the predator was positively correlated with lizard's endurance capacity, i.e., by push-ups the lizard was communicating to the snake its alertness and that is able to escape an attack. However, endurance was not correlated with lizard's body size, so the snake was not able to evaluate the ability of the lizard to escape based on its visual bodily qualities. Therefore, the author concluded that: "predation pressure and sexual selection may simultaneously favor the evolution of honest communication to allow both the predator and the potential mate or male rival to assess individual quality using the same signal" (Leal 1999).

Animals with conspicuous colors and specific body structures, such as some amphibians and insects, are honestly signaling that they are unpalatable. Their appearance is selected by evolution because predators learn to avoid animals with such prominent warning signals (Shettleworth 2010).

## Conclusion

In the animal kingdom, honest signaling is shaped by evolution but is liable to change by environmental conditions. Finally, plants may also use signals that can be honest or dishonest, when communicating with animals.

## Hood's Gravity Rules

Emma C. Tecwyn<sup>1</sup> and Daphna Buchsbaum<sup>2</sup>

<sup>1</sup>Cardiff University, Cardiff, UK

<sup>2</sup>University of Toronto, Toronto, ON, Canada

## Synonyms

[Gravity bias](#); [Gravity error](#); [Naïve physics](#); [Tubes task](#)

## Definition

The gravity bias or gravity error is the naïve expectation that an unsupported object will fall straight down, regardless of any obstacles that impede, constrain, or divert its trajectory. This bias is typically revealed by participants making “straight down” search errors in action-based tasks, most strikingly in the tubes task (Hood 1995). Specifically, when an object is dropped down an opaque diagonal tube, an individual exhibiting a gravity bias makes a predictable error: they search the location directly beneath the top of the tube that the object is dropped into (“A” in Fig. 1a, b), rather than searching the correct location that is connected to the bottom of the tube (“C” in Fig. 1a, b). According to Hood’s (1995, 1998) account, an important feature of a naïve gravity bias is that the error is challenging to overcome and persists in spite of counter-evidence. In the tubes task, this is exemplified by repeated searching of the gravity location across trials, despite seeing the actual end location of the object each time.

## Hood's Discovery of the Gravity Bias in Young Children

The gravity bias was first discovered by Bruce Hood (1995), who set out to investigate the development of spatial reasoning abilities in young human children (2- to 4.5-year-olds) using the

**Hood's Gravity Rules,**

**Fig. 1** Versions of the tubes task typically used with (a) human children (three intertwined tubes) and (b) non-human animals (single diagonal tube).  
*A* = gravity location,  
*B* = middle location,  
*C* = correct location

tubes task. In the original version of the task, children were presented with a frame containing between one and three opaque, intertwined tubes, each connected to a cup at the base of the apparatus (Fig. 1). The apparatus was designed so that the top of each tube had a cup directly beneath it (aligned), but the bottom of that tube was always connected to an alternative cup (nonaligned). Children watched an experimenter drop a ball down one of the tubes and were then encouraged to search for the ball. The experimenter then switched the position of the tube(s), dropped the ball down one of them again, and the child searched again (Hood 1995, Exp. 1). This was repeated across multiple trials for one-, two-, and three-tube versions of the task. To an adult, it seems obvious that the ball will end up in the cup connected to the end of the tube that it was dropped down – you simply have to follow the path of that tube from top to bottom. However, while 4-year-olds generally succeeded at all versions of the task regardless of the number of tubes, children up to around 3.5 years of age struggled to locate the ball when multiple tubes were intertwined, and most 2-year-olds could not even pass the simplest one-tube version (Fig. 1b; Hood 1995).

In examining children's search errors, Hood observed something intriguing: when children searched incorrectly, regardless of their age and the number of tubes, their errors were not randomly distributed; rather, they tended to search the cup aligned directly beneath the top of the tube that the ball was dropped into, or the "gravity location" ("A" in Fig. 1a, b). We will refer to searching the gravity location as the "gravity

error." Furthermore, even though children were allowed to continue searching until they found the ball on each trial, which meant they received visual feedback regarding the actual end location of the ball, children did not make this mistake only once and then succeed on their next trial; this erroneous searching of the gravity location persisted across multiple presentations of the task.

To see whether it might be the case that switching the configuration of the tube(s) between trials was confusing for the youngest children, causing them to default to searching the gravity location, Hood presented ten 2-year-olds with a simplified version that we will call the "diagonal tube task" (Hood 1995, Exp. 4; Fig. 1b). This version involved a single diagonal opaque tube that was configured top-left to bottom-right of the frame and remained in a fixed position across trials. However, even in this relatively straightforward version of the task, the majority of 2-year-olds persisted in searching the gravity location (bottom left) across trials (trial 1: 9/10, trial 2: 8/10, trial 3: 9/10; overall gravity searches: 62%; Table 1).

This demonstrates that even when the task is visually less confusing and children are given the opportunity to learn where the item ends up (because it ends up in the same place on every trial), 2-year-olds show a persistent gravity bias according to their search behavior (Hood 1995). Nine out of the ten children tested eventually learned to solve this task (based on a criterion of five consecutive correct searches), after which the configuration of the tube was switched so it was positioned top-middle to bottom-left of the frame, and a single trial presented. Five of the nine

children reverted to a gravity bias and searched the new gravity location (the bottom middle location), suggesting that they had previously learned to succeed based on reinforcement (i.e., learning the correct location to search across trials), rather than coming to understand the tube’s physical-causal mechanism. The gravity bias is described as “theory-like” on the basis that, like formal theories, it produces behavior that is initially challenging to overcome (Hood et al. 2006), even in the face of contradictory evidence, as exemplified by perseverative search of the gravity location despite receiving visual feedback regarding the correct end location of the ball.

Subsequent Developmental Studies

Since Hood’s (1995) seminal study, the gravity bias seen in young children has been shown to be a robust effect that has been replicated across several different studies and research groups (e.g., Bascandziev and Harris 2010; Baker et al. 2011; Freeman et al. 2004; Hood et al. 2006; Jaswal 2010; Joh and Spivey 2012). In the following section, we discuss studies that have attempted to uncover the mechanisms underpinning young children’s gravity bias, as well as how children are ultimately able to overcome

searching on the basis of this bias. These studies suggest that (1) understanding the causal mechanism of the tube and (2) inhibitory control both have a role to play.

Understanding the Causal Mechanism of the Tube

Although at first glance solving the tubes task appears fairly simple, knowing how the hollow tube affects where the dropped object will end up requires several pieces of knowledge about the physical world. Necessary prerequisites for searching correctly in the tubes task include knowledge of object permanence, invisible displacement, object solidity, containment, gravity, and how these factors interact to constrain the path of the object through the tube. It is therefore possible that young children fail to locate the reward because they do not understand the tube’s causal mechanism; i.e., that it is hollow and constrains the reward’s path as it travels through it.

Indeed, there is evidence that acquiring knowledge about the physical-causal mechanism of the tube is important for success in the tubes task and results from other tasks suggest that physical reasoning skills do improve between 2- and 3.5-years (Seed and Call 2014). Several studies have shown that manipulations to the tubes task that highlight

the causal role of the tube in some way can improve performance and reduce searching of the gravity location. Modifications that have enabled children to perform better include: making the openings at the top of the tubes more visible (Bascandziev and Harris 2011); verbal testimony about the causal role of the tube in constraining the object's movement (Bascandziev and Harris 2010); instructing children to imagine the ball rolling down the tube (Joh et al. 2011; Palmquist et al. 2018); and making the tubes different colors to accentuate their separate trajectories (Joh and Spivey 2012). Thus, better understanding of the tube's causal mechanism likely contributes to children's ability to overcome their gravity bias by around 4 years of age. However, as another series of studies suggests, poor understanding of the tubes' causal mechanism does not fully explain younger children's gravity-biased search.

### Gravity-Specific Bias

If a general inability to understand the causal mechanism of the tube was the sole factor leading children to make a gravity error, then they would be expected to make a comparable error in other tasks involving the invisible displacement of objects through tubes. For instance, it is possible that searching the "gravity location" could reflect a more general incorrect causal belief that moving objects travel in a straight line, or a default strategy of searching the location closest to where the object was dropped from.

However, this does not appear to be the case. In one study, when children were shown video footage of the tubes task that involved upwards motion (where the ball was "sucked up" a tube), they were more likely to correctly identify the end location of the ball compared with when the task involved downwards (i.e., gravity-based) motion (Hood 1998). A horizontal version of the tubes task revealed a similar pattern of results (Hood et al. 2000) – 2-year-olds who were presented with both vertical and horizontal trials with the tubes apparatus were more successful at locating a ball when it moved horizontally through a tube compared with when it fell vertically. Children's better performance in versions of the task involving upward and horizontal motion demonstrates

that children who exhibit a gravity error in the original version of the tubes task are better able to understand the tube's physical mechanism under other conditions. These findings provide evidence that the nature of young children's search error in the tubes task is specific to falling/gravity-based displacement events, as opposed to being explained by a more general straight-trajectory bias or a proximity bias.

Taken together, these studies suggest that the gravity error in children reflects a naïve theory that all dropped objects fall straight down, even if their path is constrained or redirected. Why might a gravity specific bias exist? It seems likely that the gravity error is based on experience of the ubiquitous influence of gravity on objects in the world, specifically, experience of observing falling objects and seeing where they land (Hood et al. 1999, 2000). Indeed, in most cases objects *do* in fact land straight below the location they fell from, so this is usually a sensible heuristic to follow. Data from humans infants seem to support this idea: 4-month-old humans are not sensitive to the influence of gravity on falling objects according to a looking-time measure (Spelke et al. 1992), and even at 10-months infants do not seem to expect an object travelling in a straight line to continue to do so (Spelke et al. 1994). However, with the development of motor skills, experience of dropping objects increases in frequency which could lead to the development of a gravity bias.

### Inhibitory Control

Inhibitory control – specifically, the ability to inhibit responding on the basis of a naïve theory of gravity – is also thought to play a central role in the ability to correctly search for the object in the tubes task. Children's performance in the horizontal and upwards tubes tasks suggests that their naïve gravity bias may be competing with their emerging understanding of the tubes' causal mechanism, leading to poorer performance when the two are in conflict, and the gravity bias must be inhibited. Evidence for the role of inhibitory control in successful performance in the tubes task comes from a study showing that 4-year-old children who pass the standard 3-tube version of the

task revert to searching the gravity location if two balls are dropped simultaneously, thus increasing the task's attentional demands and cognitive load (Hood et al. 2006). Additionally, 3-year-olds' ability to search correctly in the standard version of the task was significantly correlated with their performance in an unrelated task where it was necessary to inhibit a prepotent response (Baker et al. 2011), suggesting that an ability to inhibit an underlying gravity bias might be playing a role in their performance.

Thus, it seems that in the case of the original version of the tubes task, children's tendency to search the vertically aligned container is best explained by a bias that is specific to gravity-based invisible displacement. At 2 years of age, children may lack complete understanding of the tube mechanism and also have relatively weak inhibitory control skills, and so are unable to inhibit searching on the basis of their gravity bias. Older children (i.e., 4-year-olds) who have developed sufficient inhibitory skills and an understanding of the tube's causal mechanism typically search correctly, but revert to gravity-based search when their cognitive skills are taxed, thus suggesting that the bias continues to exist, but is usually "dormant."

### Explicit Versus Implicit Measures of the Gravity Bias

All of the tubes task studies discussed so far have used search behavior as a measure of understanding; i.e., they have all used action-based ("explicit") measures. However, in addition to possessing the prerequisite knowledge about the physical world to be able to infer where the object will end up, and being able to inhibit responding on the basis of a gravity bias, asking participants to search for the object also necessitates holding a representation of the object in mind and generating an appropriate search response. It is possible that the additional demands posed by requiring participants to search for the item tax young children's limited cognitive resources and thus contribute to gravity-biased search. To investigate whether this is the case, different measures based

on, e.g., looking-time or gaze direction ("implicit" measures), which eliminate the additional task demands, can be used.

Only one study (Lee and Kuhlmeier 2013) has explored how children perform in the tubes task according to an implicit measure. Two-year-olds were presented with one-tube and two-tube versions of the task. However, rather than allowing participants to search for the ball, Lee and Kuhlmeier (2013) measured their eye gaze patterns (implicit measure) and pointing behavior (explicit measure). In the one-tube version, all children directed their gaze to the correct location, but only some also pointed to this location. In the two-tube version, neither looking nor pointing was directed to the correct location. When children made pointing errors, they tended to be directed at the gravity location, corroborating the findings of previous studies where children had to actively search for the object (Hood 1995). However, some children who incorrectly pointed at the gravity location in the one-tube version directed their gaze to the correct location at the end of the tube (when there were two tubes, which increased the complexity of the task, 2-year-olds both looked and pointed at the gravity location). Thus, according to their spontaneous eye movements, some 2-year-olds were implicitly aware of the end location of the ball in the one-tube version of the task, even though they were not able to elicit a correspondingly correct pointing response. This provides evidence for a potential dissociation between implicit and explicit measures in the diagonal tube task: some children's eye-gaze was directed towards the correct location, whereas their pointing behavior appeared to be guided by a gravity bias (Lee and Kuhlmeier 2013). Based on current evidence, it is not clear what might explain this dissociation between the two behavioral measures; differences in processing load (with pointing demanding more processing resources than spontaneous looking), or the nature of the underlying representation required to support the different behaviors (a stronger representation is required to guide pointing than gaze), are both plausible.

The studies discussed so far provide evidence that 2-year-old children show a clear gravity bias

in the tubes task, especially according to the search-based measure typically used. This bias is resistant to counterevidence – it persists across repeated trials, even if there is only one tube and the apparatus remains configured in the same way – and is evident until a later age if more tubes are intertwined. Eventual success in the task at around 4 years of age seems to depend on (a) being able to understand how the tube constrains a falling object's movement and (b) possessing sufficient inhibitory control skills to suppress inappropriate responding on the basis of a naïve gravity bias.

In the next section, we present comparative work with nonhuman animals that has aimed to investigate whether a gravity bias might be shared across species, or conversely, could be unique to human children. Do other species also exhibit a comparable error when searching for objects invisibly displaced by gravity?

## Nonhuman Animal Studies

Might a naïve theory about the trajectory of falling objects be unique to humans, or do other species also exhibit a gravity error when searching for invisibly displaced dropped objects? The ability to track and locate objects that have moved out of sight is an ecologically relevant problem for many species (Hauser et al. 2001). Terrestrial and arboreal species in particular – especially those that forage for food that falls to the ground – frequently experience the effects of gravity on unsupported objects. It is therefore reasonable to expect that they, like children, might have a naïve gravity bias, and indeed it has been claimed that nonhuman species including monkeys (Hood et al. 1999) and dogs (Osthaus et al. 2003) do have a gravity bias.

The tubes task was designed for use with preverbal children, and its simplicity makes it suitable for conducting comparative studies with diverse nonhuman species. It is possible to implement the task without using verbal instructions, with relatively little pretraining, and the motor demands are minimal. Several studies have adapted the tubes task – mainly using the single

diagonal tube task of Hood's (1995), Exp. 4 (Fig. 1b) – to examine performance in nonhuman animals and how it compares to that of human children. The aim of these studies has been to shed light on the mechanisms underpinning the gravity bias and enhance our knowledge of the nature and origins of theory-like physical reasoning and cognitive mechanisms more generally. We discuss these studies in the following sections.

## Nonhuman Primate Studies

The majority of nonhuman studies using the tubes task have focused on our closest relatives – the nonhuman primates. In the first nonhuman study, nine cotton-top tamarins (*Sanguinus oedipus oedipus*) were presented with the diagonal tube task (Hood et al. 1999). Seven out of nine individuals searched the gravity location in their first trial, providing evidence for an initial gravity bias in this species (Table 1).

However, in their second trial only 2/9 monkeys searched the gravity location, and across all trials only 39% of searches were directed at the gravity location. Therefore, while this study provides the most compelling evidence to date that a nonhuman species' search behavior might initially be guided by gravity, this pattern of dramatically reduced searching of the gravity location in trial 2 does not fit the "challenging to overcome" criterion proposed by Hood (1998) when describing the gravity bias he observed in young children.

Additionally, tamarins that had previously participated in a horizontal version of the diagonal tube task did not exhibit a gravity bias when subsequently presented with the vertical version, even in their first trial (Hauser et al. 2001). This suggests that any gravity bias may not be very robust in this species and can be overcome with experience of food moving through tubes in a nongravity-based context. In contrast, 2-year-old children who participated in a transparent version of the vertical tubes task (and were able to solve it) still exhibited a gravity bias when they were tested with the opaque version immediately afterwards (Hood 1995).

Findings from subsequent studies with monkeys and apes further suggest that the gravity bias might in fact not be a phylogenetically widespread

phenomenon, even within primates. Only 4/7 common marmosets (*Callithrix jacchus*) searched the gravity location in their first trial of the diagonal tube task, and only 39% of all trials in session 1 of the study were directed to the gravity location (Cacchione and Burkart 2012; Table 1). A looking-time version of the task showed that, similarly to young children directing their gaze towards the correct end location (Lee and Kuhlmeier 2013), marmosets looked longer when the object was revealed to have ended up in the impossible gravity location, compared with when it ended up in the correct location (Cacchione and Burkart 2012), demonstrating a lack of a gravity bias according to this implicit measure.

Two studies have used versions of the tubes task to investigate whether nonhuman great apes have a gravity bias. A study by Cacchione and Call (2010) presented all four nonhuman great ape species with the standard diagonal tube task. Apes searched randomly in trial 1, but more individuals searched the correct location than the gravity location, and the overall number of gravity searches in session 1 of the experiment was low at around 20% (Cacchione and Call 2010; Table 1). However, when apes did make an error, they were significantly more likely to search the gravity location than the middle location, suggesting that apes may indeed hold naïve beliefs about gravity, but they are usually able to suppress acting on the basis of this belief when it is inappropriate. On the basis of these results, it has been suggested that great apes might be less susceptible than monkeys and 2-year-old children to making gravity errors because of their superior inhibitory skills – it is not necessarily the case that apes do not have naïve beliefs about the influence of gravity on unsupported objects; it could just be that they are better able to suppress acting on the basis of this bias (Cacchione and Call 2010).

In addition, several of the apes in this study had previously completed an “acoustic” version of the task, in which they were able to hear the reward rolling down the tube, thus providing information regarding the causal mechanism of the tube. Since causal mechanism information improves children's performance, it is difficult to know how this experience might have influenced apes'

subsequent performance in the traditional “silent” version of the diagonal tube task, rendering direct comparisons of the ape data with data from other species problematic.

The findings of an earlier study by Tomonaga et al. (2007) supports the possibility that great apes might have a gravity bias that they are able to inhibit. Tomonaga and colleagues presented immature and adult chimpanzees (*Pan troglodytes*) with a task involving two crossed tubes, but rather than searching for the object after it had been dropped down the tube, chimpanzees had to predict where the object would appear by putting their hand at the bottom of one of the tubes before it was released. The authors reported that chimpanzees in both age groups consistently selected the gravity location directly beneath where the reward was held, providing some evidence that chimpanzees' reasoning about the trajectory of falling objects might be influenced by gravity. Based on the results of these two studies, it is possible that apes are able to solve the single diagonal tube task, but reveal a gravity bias when the task is more complex because more tubes are intertwined, which is known to increase children's preference for the gravity location (Hood 1995; Lee and Kuhlmeier 2013). However, given that there were other differences between tasks in addition to the number of tubes – two versus three search locations; prediction – versus search-based measure – it is difficult to compare these findings directly with the other nonhuman studies discussed in this section.

Overall, there appears to be mixed evidence for gravity biases in nonhuman primates. While there is evidence that the search behavior of all of the species tested to date is influenced by gravity to some extent – tamarins searched the gravity location in trial 1 (Hood et al. 1999), marmosets were more likely to search the gravity than the middle location when they erred (Cacchione and Burkart 2012), as were apes with a single tube (Cacchione and Call 2010), and chimps with two crossed tubes showed the most compelling gravity bias (Tomonaga et al. 2007) – whether the performance of any of these species is indicative of a naïve theory of gravity comparable to young children's is less clear.

### Domestic Dog Studies

To date, the only nonprimate species to have been presented with the diagonal tube task is the domestic dog (*Canis familiaris*; Osthaus et al. 2003; Tecwyn and Buchsbaum [accepted](#)). Osthaus et al. (2003) found that 8/16 dogs searched the gravity location in trial 1 and this proportion decreased steadily across repeated trials (Table 1). Despite this weak evidence for an initial gravity bias in dogs, this paper has often been interpreted in the literature as demonstrating that dogs have a robust gravity bias – at least initially – in the diagonal tube task (e.g., Bascandziev and Harris 2011; Cacchione and Call 2010; Joh et al. 2011; Tomonaga et al. 2007). A recent study that replicated and extended the diagonal tube task with dogs also found no evidence that this species searches on the basis of a naïve gravity bias, either in their very first trial (5/16 gravity searches), or across all trials (16% of searches directed to the gravity location; Tecwyn and Buchsbaum [accepted](#); Table 1). Dogs in this study also did not search correctly immediately, and in some modified versions of the task, they failed to learn to search correctly even across multiple trials, which suggests that they may be particularly poor at understanding the tube's causal mechanism.

### Conclusion

Two-year-old children show a compelling gravity bias in even simple versions of the tubes task, and this bias is also seen in children up to around 3.5 years of age when multiple tubes are intertwined. This finding is robust and has been replicated across multiple studies. The evidence that any nonhuman animals possess a gravity bias – at least to a comparable extent to young children – is less conclusive. Despite being widely described as having a gravity bias across the literature, there is currently little evidence for a gravity bias in dogs. It is possible that the search behavior of some monkey species is initially guided by gravity (e.g., cotton-top tamarins; Hood et al. 1999), but there is little evidence that this gravity-biased search persists across

multiple trials, and thus an important criterion of a naïve gravity bias according to Hood (1995, 1998) – resistance to counterevidence – is not met. The most suggestive evidence of a gravity bias was found in the great apes, who may show a gravity bias when multiple tubes are intertwined, similar to 3-year-old children. At present, whether and to what extent any nonhuman species share young children's persistent gravity bias remains an open question that warrants further investigation.

### Current Limitations and Future Directions

Several factors limit the extent to which it is possible to make valid comparisons between different species. Given that there is evidence that the number of tubes influences children's performance in the task and the extent to which they exhibit a gravity bias (Hood et al. 1995; Lee and Kuhlmeier 2013; Palmquist et al. 2018), this makes meaningful comparisons between existing child and nonhuman animal studies challenging. It is possible that if the apparatus was more complex (i.e., more tubes were intertwined, as in the majority of developmental studies), nonhuman animals would also be more susceptible to a gravity bias – and indeed there is some evidence from chimpanzees to suggest that this is the case (Tomonaga et al. 2007). Several other methodological inconsistencies between studies with children and nonhuman animals (and indeed between different nonhuman animal studies) render valid cross-species comparisons tricky, including: whether the tube configuration is variable or fixed between trials; differences in pretraining procedures; differences in the number of test trials presented; variation with regards to prior experience with related tasks; and a lack of availability of trial-by-trial data.

Future work should address these issues by replicating the existing nonhuman studies with larger samples and also by systematically manipulating the number of tubes in the apparatus to see if/whether this influences the strength of the gravity bias. Extending the paradigm to additional species that are known to differ with respect to their causal reasoning abilities, inhibitory skills, and ecology in terms of the extent to which they

have experience of the effect of gravity on unsupported objects could be particularly valuable for improving our understanding of the mechanisms underpinning gravity-biased versus successful performance in the tubes task. A developmental comparative approach that examines performance in both immature and mature individuals across species would enable us to better understand the evolutionary origins of naïve beliefs about gravity.

## Introduction

Hormones are secretions from the ductless glands (known as endocrine glands) and specialized cells in the specific animal organs, which circulate through blood to reach target destinations in specific parts of the body (including the brain) for action.

Modern view for the hormones is that a hormone is any substance that acts at the cellular level to initiate, stop, or modulate a cellular process, and they include all chemical messengers synthesized by the body that act by binding with high affinity to target cells within the same individual. Some scientists also consider pheromones as hormones. Pheromones are those molecules which act in a

similar way as hormones – leave the body of one individual to act on another individual. The site of action can be nearby or at a distant target.

Hormones can act via paracrine, autocrine, or intracrine mechanisms. A hormone may act both locally and at distant target sites traveling through the bloodstream. To enter the brain, hormones have to cross the blood-brain barrier (BBB) which has differential regulation for specific hormones and also come in direct contact with the neurons in certain brain regions lacking a natural BBB. Conversely, some hormones which are synthesized inside the brain have to cross the BBB to reach to the target sites present in the periphery. In the brain, hormones alter neural transmission at synapses and induce other neuroplastic changes, which, with their concomitant action on the peripherally present neuromuscular effectors, influence neurophysiological functions pertinent to a behavior.

“Hormone” comes from the Greek word *hormon* which literally meant “to set in motion,” providing a clue for its inductive influence on the behavior. Relation of the hormone with behavior is a complex phenomenon that cannot be explained in the terms of direct causality. Both show a kind of mutual dependence and certain important to note intricacies. A hormone itself doesn’t generate a behavior but creates a homeostatic conditioning conducive for its occurrence, i.e., it increases the chance that the organism will show a particular behavior when physiological and environmental conditions are optimum.

Empirical studies have shown that almost all the aspects of behavior are influenced by hormones – including survival, sovereignty, circadian functions, feeding, reproduction, and proliferation of the organisms. The specific branch of the behavioral science devoted to study hormonal influences on animal behavior is known as “behavioral endocrinology.”

New advances and research updates in the field have given “behavioral endocrinology” an edge in explaining humoral bases of animal behavior. An emerging concept “epigenetics” has revolutionized this field providing the mechanisms for how the hormonal influences on the behavior get tagged to the genetic structure of the organism which not only may persist for the life time but may also presumably pass into the next

generations. This chapter is aimed to provide a summarized account of the basic concepts and mechanisms, applied implications, and research updates in “hormones and behavior.”

## Hormones: Basic Handcuff

(Types and structure, sources, mechanisms of action, physiological effects)

### Types and Structure

The prototype chemical structure of the hormones is that of a protein, but some are also peptides, amines, or steroids. The protein, peptide, or amine hormones are water soluble and hence cannot enter into the cell directly; in contrast, steroid hormones are lipid soluble and hence can enter inside the cell directly. Lipid soluble hormones act slow but their effects last longer than water-soluble hormones.

### Sources

Hormones are synthesized and secreted chiefly by the endocrine organs – which are either components of the brain or situated peripherally in the body – and also by the specific tissue components of the other organs such as the heart and kidney (Table 1).

The endocrine organs and specific hormone-secreting cells (inside the other organs) in response to the neural stimuli (or humoral cues released from specific hypothalamic nuclei) release their secretions in the venous blood draining those organs. In their further course, from the venous tributaries, hormones reach to the central blood channels from where through the arterial branches they get distributed to the target organs (including the brain).

### Local Synthesis by Cortical Neurons

Certain hormones (including sex hormones) are synthesized locally by cortical neurons in specific brain regions (in addition to their prime secretion from endocrine organs) and get delivered through their axons to the targeted brain regions which contain receptors for specific hormones (Table 2). Hippocampus neurons are known to secrete sex hormones and express their receptors (Ish et al. 2007).

### Mechanisms of Action

Biologically effective amounts of hormones are very minute which get usually measured in micrograms ( $\mu\text{g}$ ,  $10^{-6}$  g), nanograms (ng,  $10^{-9}$  g), or picograms (pg,  $10^{-12}$  g).

A hormone other than steroid (except thyroid hormones) attach to the receptors present on the surface of target cells creating the hormone-receptor complex, which in turn engages a G protein-dependent secondary messenger pathway (like cAMP, cGMP, diacylglycerol,  $\text{Ca}^{++}$ , etc.) to induce protein kinases/phosphorylases related to specific biological events. Steroid hormones, being lipid soluble, may additionally enter into the cell to reach nucleus tagged with transporters or binding protein present in the cell cytoplasm, where they set free from the carrier molecule and attach to the nuclear receptors (binding sites) at DNA promoter regions for the genes assigned for forming specific proteins (Fig. 1).

Although thyroid hormones are chemically amine, their three-dimensional structure resemble that of the steroid hormones and hence can enter the cell and reach to the specific nuclear receptors with the help of specific transporters present at the cell membrane (facilitated diffusion) and in the cell cytoplasm.

Hormones coordinate an animal's physiology and behavior by managing its bodily functions. Hormones are functionally similar to the chemical mediators including neurotransmitters and cytokines and also interact with them in influencing a behavior. They often function locally as the neurotransmitters.

Hormones may synergize or antagonize with each other in influencing a behavior. For example, various sex hormones released during ovulation in a female add up their effects inducing a reproductive behavior; in contrast, the estrogen which is followed by the progesterone in the menstrual cycle induces opposite behavioral effects.

### Endocrine System and Physiological Effects of Hormones

Classically, the endocrine system of the body has three main components: a brain part, pituitary (anterior part), and target endocrine organ. Neurosecretory cells in the brain (as in hypothalamus) synthesize releasing/inhibitory neurohormones, which reach to the pituitary gland via

**Hormones and Behavior, Fig. 1** Mechanisms of action a. Protein, peptide, and amine hormones b. Steroid and thyroid hormones

hypothalamic-hypophyseal portal system and stimulate the pituitary gland to secrete its products into the general blood supply of the body. Pituitary hormones stimulate target cells in the endocrine organ to secrete specific hormones. In the brain, the output hormone has a negative feedback loop, regulating the brain's secretion of neurohormones. This three-tier system of control operates for all endocrine organs in the body such as the gonads and adrenal and thyroid glands, though all hormones don't follow the three-tier system as those secreted from posterior pituitary (posterior part of the pituitary is considered as extension of the brain and secretes oxytocin and vasopressin which have important physiological and behavioral effects) and from specific cells of the brain (other than the hypothalamus) or other bodily organs (Table 1).

Hormones are involved in the maintenance of physiological functions not only involved in day-to-day activities like sleep, feeding, drinking, etc. but also that with prolonged course of effects like reproduction, growth, aging, immunity, etc. (Table 1). Hormonal regulations of the physiological processes have been co-opted with the behavior linked to these processes in the evolutionary course to ensure better survival of the organism.

## Behavioral Endocrinology As a Discipline

### History

George Montagu in 1802 had noted that songbirds sing more at the times of the year when their testes are larger. The first study of behavioral endocrinology as per records was done by Arnold Adolph Berthold in 1846. Berthold showed that male typical behavior could be restored by reimplanting the testes in the cockerel birds (what they had lost following the castration). He thought it is caused by certain substances – androgens – secreted from the testes (Fusani 2017).

Further founding works in this field were done by Frank et al., using domestic or laboratory animals. In 1960, the advent of radioimmunoassay

(RIA) had allowed to measure hormones in small blood samples. RIA had revolutionized behavior endocrinology research because it made easy to study in living animals and to keep them alive for further observations and follow-ups or involve human subjects (Fusani 2017).

## Commonly Used Investigations and Experimental Methods

The concentration of hormones in the blood or serum in the living animal can be investigated with the immunoassays (radioimmunoassay, enzyme immunoassay, and fluorescence immunoassay) and more recently high-performance liquid chromatography (HPLC) and mass spectrometry combined with gas chromatography (MS-GC). The general investigations used for in vitro determination of hormones or their receptors are immunocytochemistry (ICC), autoradiography, in situ hybridization, and blotting. Brain imaging techniques (like PET scan and f-MRI) which reveal brain activation during certain behaviors, paired with endocrine manipulations or monitoring, can provide important information about hormone-behavior interactions (Fusani 2017).

Standard scientific approaches to experimentally manipulate the hormonal production and observe the resultant change of behavior are mentioned below:

**Ablation:** A hormone-dependent behavior disappears when the source of the hormone is removed or the hormone actions are blocked – it is done by surgery (an endocrine organ is removed), antagonist or blocker (hormone receptor is blocked), or gene knockouts.

**Replacement:** Restoration of the missing hormonal source or its hormone restores the absent behavior – it is done by hormone implants (planted under skin), agonists or mimics (induce signaling cascade acting on the hormone receptor), and natural or engineered gene mutation.

**Hormone-behavior correlation:** Behavior is studied for the covariation with the changing concentrations of the hormone.

## Hormonal Homeostasis and Its Linking to Behavior

Major hormonal centers in the body work in unison in attempt to maintain a state of functional equilibrium with each other and put an accumulative influence on the neurocognitive functions, which is reflected in the behavioral performance of the animal. The hypothalamus in association with the anterior pituitary and adrenal gland constitutes HPA axis – the central axis in the body maintaining neuroendocrine homeostasis. HPA axis is extremely important for the development of adaptive behavior – which is necessary to deal with the stress. A parallel axis connecting the hypothalamus and anterior pituitary to gonads (testis in male and ovary in female) constitutes HPG axis. In HPG axis, release/inhibitory hormones are secreted from specific hypothalamic nuclei which induce synthesis/release of stimulating/luteinizing hormones from anterior pituitary which in turn induce synthesis/release of sex hormones from the gonads (Table 1) which makes basis of sexual and reproductive behavior in both sexes.

Extensive connections of the hypothalamic nuclei to the key brain regions especially that dealing with the emotion, learning, and memory make HPA axis crucial in behavioral endocrinology.

Uniquely, HPA axis components don't connect to each other through neural pathways, but regulatory instructions and feedbacks between the axis components reach through the blood. A venous portal system from the hypothalamus carries corticotrophin-releasing hormone (CRH), released from the paraventricular nuclei (PVN) to the anterior part of the pituitary (adenohypophysis) where they stimulate/inhibit release of adrenocorticotrophic hormone (ACTH). ACTH in the blood stimulates release of cortisol/corticosterone (a glucocorticoid) from the adrenal gland cortex, which is directly released in the veins draining this organ and through the blood reaching to the target destinations, which express glucocorticoid receptors (GR) for action.

HPA axis mediated neuroendocrine homeostasis, and consequent neural stabilization of

cognitive domains of the brain is largely involved in maintenance of healthy behavior. HPA axis responses to the stimuli are controlled by negative and positive feedback loops running between the HPA centers and target destinations. A positive feedback should increase the hormonal secretion, and vice versa a negative feedback should in turn decrease the hormonal secretion. Though, a positive feedback loop is less common in practice than the negative feedback loop in HPA axis regulation. Final command for the feedback loops comes from the hypothalamic nuclei (through releasing or inhibitory hormones). Functionally, HPA axis extends to the limbic cortex of the brain (HPA-L axis – the limbic cortex deals with the emotion and affective behavior and contains amygdala, hippocampus, medial prefrontal, insular, and cingulate cortices as chief constituents. Different limbic system components may have varying influence on HPA axis as has been noted between the hippocampus and amygdala (Fig. 2) (Kumar et al. 2017a). A dysregulation of extended HPA axis has been extensively implicated in the genesis of stress-induced behavioral pathologies (Phillips et al. 2006; Kumar et al. 2017a).

## Circadian Control of Hormone-Regulated Behavior

Specific nuclei in the hypothalamus, namely, suprachiasmatic (SCN) and paraventricular nucleus (PVN), regulate timed release of hormones. The pineal gland is also known to maintain timed release of melatonin which depends on exposure of the organism to the light (Tsang et al. 2014). The circadian releases of the hormones from the hypothalamic and pineal nuclei are affected by the duration and intensity of the light the organism is exposed to. The information of the light exposure reaches to the SCN and other hypothalamic nuclei through bidirectional retinohypothalamic connections (Tsang et al. 2014). Pineal gland nuclei are also connected (Tsang et al. 2014). Control of circadian rhythm through SCN and PVN nuclei is a complex biological process which is conserved among species and genetically determined (Andreani et al. 2015).

**Hormones and Behavior,**  
**Fig. 2** Feedback  
regulations at extended  
HPA-L axis

The molecular repertoire of the SCN has been presented in brief in Table 3.

The molecular repertoire maintaining circadian rhythms were found present in many bodily organs and tissues, which together create a complex molecular network system which gets its central command from SCN (Hughey and Butte 2016).

Cortisol, the HPA axis output hormone, also follows circadian rhythm, with its peak secretion in the morning with lesser serum values along the day. A dysregulation of circadian synthesis/release of cortisol was found implicated in stress-induced psychiatric disorders (Kumar et al. 2017a, b).

**Blood-Brain Barrier (BBB): A Body-Brain Interface in Hormonal Action**

**Crossing Blood-Brain Barrier (BBB)**

A hormone would pass through the BBB or not depending on its chemical structure. Steroid hormones are lipid soluble and hence can easily pass to-and-fro through the BBB (the peripherally synthesized hormones enter the brain and those

**Hormones and Behavior, Table 3** Molecular repertoire of SCN

| Casein kinase 1 (ck1) δ, ε                     |

synthesized inside the brain reach to periphery), but protein, peptide, amine, and other non-lipid hormones can do it with help of the transporters/ binding proteins only. Availability of the transporters/binding proteins in the blood makes passage of lipid-insoluble hormones a saturable/ rate-limited process.

**No BBB in Selective Brain Regions**

Selective sites of the hormone synthesizing brain regions called circumventricular organs are devoid of a blood-brain barrier (BBB) which

**Hormones and Behavior, Table 4** BBB free regions in brain

facilitates the release of the stored hormones in the blood (Table 4).

These BBB-free regions are also the site for receiving peripherally released hormones and contain receptors for such hormones – presenting a unique opportunity for neuron-hormone interactions.

**Neuron-Hormone Interactions Inside the Brain**

**Hormone-Induced Neuroplasticity**

Hormonal exposure induces adaptive plastic changes at the neural synapses – basic unit of the information processing in the nervous system. The key brain regions involved in the neuroendocrine regulation (like amygdala, hippocampus, hypothalamus, prefrontal and limbic cortex) densely express receptors for the hormones implicated in cognitive and emotional development (like sex and thyroid hormones, oxytocin, and vasopressin).

Any change in the physiological levels of a hormone reaching the brain centers involved in a behavior-induced structural and functional changes at the synapses – alter membrane excitability, induce synaptic protein formation and activate membrane signaling cascade, and alter presynaptic release of neurotransmitters and/or response at postsynaptic membrane – in turn influences synaptic transmission. Hormonal influence is also evidenced in the formation of the new synapses, neurite outgrowth and spine density, dendritic arborization, myelination, neural

connectivity, and other parameters of the neuroplasticity. Additionally hormonal stimulation induces release of neurotrophins, mainly brain-derived neurotrophic factor (BDNF), which shows neural activity-dependent secretion in the cognitive domains of the brain and can induce the analogous neuroplastic changes (Kumar et al. 2017b).

Estrogen has a significant role in both sexes in improving learning and memory acting at hippocampal neurons which are known to synthesize estrogen locally and also densely express receptors for it. These synaptic and other neuroplastic changes are remodeled with further hormonal level changes to reinforce or weaken a behavior. Hormone-induced neuroplastic changes supposedly create a basis for such more changes in future – a neuroscience concept known as “meta-neuroplasticity” (Salma 2014). Behavior-specific neural networks get hormonal modulation when challenged with specific stimuli. Release of a hormone in response of a stimulus is orchestrated by specific hypothalamic nuclei – which is the command center for the synthesis/release of all hormones. Hormones specifically induce synthesis/release of various neurotransmitters/modulators in different parts of the brain. Unique of the steroid receptors present in the brain is that they may be activated by the neurotransmitters and intracellular signaling systems other than the cognate hormone by a process known as ligand-independent activation (Blaustein 2004). Together these molecules differentially modulate the components of the synaptic transmission and neural network properties. A hormone-induced neuroplasticity is specific and unique to the individuals which brings diversity in their behavior, i.e., two individuals may behave differently even in the similar environmental contexts.

**Cortical and Subcortical Control**

Hormones show region-specific influence on the cerebral cortex. The reflex-based, primitive and instinctual, emotional, and survival behaviors (fright, flight, fight!) which are common to all animals depend more on the control of the hormones and involve cortical regions which are older in evolution like the hippocampus and

dentate gyrus, olfactory cortex, and medial prefrontal/orbital and cingulate cortex. In contrast, executive behaviors like thinking, strategizing or planning, and decision making – which are salient characteristics of human – show less hormonal influence and involve newly evolved cortical brain regions like lateral prefrontal and associative regions of the neocortex.

The amygdala – a quasi-cortical structure which is the nodal brain center for the primitive behaviors like fear, rage, and anger and densely expresses receptors for many hormones like steroid (especially sex hormones and cortisol) and amine hormones, and also for oxytocin and vasopressin – shows high influences of the hormones.

Hippocampal neurons (including dentate gyrus) not only densely express receptors for the above named hormones but are also known to synthesize some sex hormones *de novo* (Table 3), especially estrogen (Ish et al. 2007). Synthesis of sex hormones in the hippocampus and expression of their receptors in this and other cortical brain regions are considered important for the sex-specific differentiation of the brain during embryonic development. Hormonal influence in the hippocampus is believed to contribute more than any other brain region owing to wider impact of the hippocampal functions in behavior. The hippocampus is the nodal region for learning and memory and also maintains functional connectivity with other brain regions. Estrogen is neuroprotective and contributes substantially to the hippocampal functions, particularly by inducing structural plasticity at synapses. Testosterone, oxytocin, and vasopressin also improve the hippocampal functions (in contrast, cortisol improves the hippocampal functions in acute exposure but diminishes in chronic exposure). Oxytocin receptor signaling in hippocampal neural circuits is thought to mediate discrimination of social stimuli and affiliation or avoidance behavior guiding social recognition (Raam et al. 2017).

Hormones also influence hippocampal neurogenesis – which has been evidenced to keep going lifelong (in dentate gyrus) and said to facilitate inclusion of new information – and hence bear an important role in learning and

memory, and a dysregulation of this has been implicated in genesis of psychiatric disorders (Kumar et al. 2017a, b). Hormonal influences on parahippocampal brain regions, especially of testosterone, are known to improve spatial performances.

Specific hypothalamic nuclei secrete hormones which reach to various target centers inside the brain and periphery through blood streams and induce release of a distinct set of hormones/neurotransmitters/modulators. Hypothalamic nuclei are also intricately connected to the cortical, sub-cortical, brain stem nuclei and spinal autonomic centers through the nerve fibers. Thus at specific hypothalamic nuclei, neural feedbacks integrate and balance with that derived from the hormones running in the circulatory system which helps the organism to respond to the internal cues like food, sex, or body temperature. For illustration, in hunger or satiety, specific hormones are released from the endocrine glands in the digestive system into the draining veins which are further carried to the parts of hypothalamus through the blood. In the hypothalamus, specific nuclei groups further transmit the impulses to the cortical neurons to create a conscious awareness of feeding status of the organism.

A miniature reign like neural structure located at the posterior limit of the hypothalamus – the habenula – which connects subcortical gray matter structures to the brainstem centers containing aminergic nuclei is known to implicate in the learning of the adaptive behavior (Kumar et al. 2017c). Habenular pathways get also influenced by the HPA axis hormonal changes which is said to be instrumental in the pathological development of submissive behaviors like social defeat (Kumar et al. 2017c).

### **Aminergic Release from the Brain Stem and Hypothalamic Nuclei: A Closer Function as Hormones**

The specific nuclear groups in the brain stem secrete aminergic/cholinergic molecules which are released at target sites in different brain regions through axonal endings (Table 5).

These molecules have the similar influences on the synaptic processing as blood-running

hormones and are referred to as neurohormones, though some of them can work like neurotransmitters (or neuromodulators) – as dopamine, serotonin, noradrenaline/norepinephrine, and acetylcholine (Tables 5 and 6). Some of these molecules are also synthesized in the hypothalamic nuclei – as dopamine, serotonin, and histamine. These aminergic centers have widespread reciprocal connections in the brain and have crucial involvement in controlling neural networks involved in emotional, survival, and adaptive behavior of the animal. The brain stem aminergic molecules in association with that released from hypothalamic nuclei help in maintaining consciousness and keeping the organism alert and also influence circadian control of feeding and sleep behavior.

| Epinephrine – reticular formation (along motor nuclei in the floor of 4th ventricle) and in periaqueductal gray |
| Serotonin – raphe nuclei                                                                                        |
| Dopamine – substantia nigra, ventral tegmental area (VTA)                                                       |
| Choline                                                                                                         |
| Pedunculopontine nucleus (PPN) – acetylcholine                                                                  |

**Hormones and Behavior, Table 6** Types of neuronal secretions in brain

|                                                                                                       |
|-------------------------------------------------------------------------------------------------------|
| A neurotransmitter                                                                                    |
| Is released at synapses                                                                               |
| Passes through synaptic cleft to affect postsynaptic neurons, a muscle cell, or another effector cell |
| A neuromodulator                                                                                      |
| Affects groups of neurons or effector cells with appropriate receptors                                |
| Often acts through second messengers and can produce long-lasting effects                             |
| A neurohormone                                                                                        |
| Is released into the blood and therefore may exert its effects on distant peripheral targets          |

**Setting of Moods, Emotions, and Impulses**

Hormones influence information transmission speed at the synapses which provide a neural substrate for the mood, emotions, and impulses in the organism. The synthesis and release of the hormones are stimulated or suppressed by the environmental cues, i.e., a prolonged exposure of the organism to a favorable environment induces synthesis/release of the particular hormones necessary to promote a behavior suitable to the context. For example, when an animal is kept in contact with a potential mate, synthesis and release of the sex hormones will show an upsurge. Similarly, exposure to a rival will upsurge release of testosterone and stress hormones – which are implicated in combating behavior.

Both male and female sex hormones by influencing release of neurotransmitters/modulators like dopamine and serotonin make an impact on mood and emotion driving an individual into reproductive behavior. A cyclical change of sex hormones during menstruation in female is associated with the mood changes/swings; women report enhanced mood in part of menstrual cycle when estrogen will have higher secretion and vice versa (Dreher et al. 2007). Some mood disorders like premenstrual or postnatal depression and perimenopausal depression (or psychosis) signify influence of estrogen in maintenance of mood in female. In male, high serum testosterone has been associated with increased concentration, visual acuity and geo-spatial abilities, positive mood, and also with the rage and impulsive behavior. Endogenous opioids, which are physiologically secreted during heavy exercise or the habitual strenuous physical activities, increase threshold for the pain and create a euphoric feeling. Internally secreted hormone-like molecules in the brain – neurohormones – which work like neuromodulators and some as also neurotransmitters (dopamine, serotonin, noradrenaline) have a critical role in setting and maintenance of the mood (Table 7).

An intricately regulated cocktail of neurohormones is said to control the rate, rhythm, coupling, and synchronization of the cortical oscillatory waves in the neurocognitive networks

**Hormones and Behavior, Table 7** Neurohormones

|                                                  |                               |
|--------------------------------------------------|-------------------------------|
| Corticotropin releasing                          | Thyrotropin releasing         |
| Hormone (CRH)                                    | Hormone                       |
| Gonadotropin releasing                           | Histamine                     |
| Hormone (GNRH)                                   | Vasopressin or antidiuretic   |
| Luteinizing hormone releasing                    | Hormone)                      |
| Hormone (LHRH)                                   | ADH or AVP                    |
| Somatostatin (growth hormone-inhibiting hormone) | Oxytocin                      |
|                                                  | Norepinephrine                |
|                                                  | Dopamine                      |
| Melanotropin release                             | Serotonin                     |
| Inhibitory factor (dopamine)                     | Melatonin                     |
| Neuropeptide Y (NPY)                             | B-endorphin                   |
| Neurotensin                                      | Agouti-related protein (AGRP) |
| Orexin A and B                                   | Estrogen                      |

of the brain – which is crucial for setting and maintenance of the mood.

Oxytocin and vasopressin which are secreted from posterior pituitary during labor and breastfeeding in female, and during sexual intercourse and intimate behavior in both the sexes, are known to have positive effect on mood and emotion. Oxytocin has a higher secretion in female and vice versa, vasopressin witnesses higher secretion in male, and their effects have been known to match to estrogen and testosterone, respectively.

**Autonomic Nervous System (ANS)-Hormone Cross Regulation**

ANS comprises of sympathetic and parasympathetic limbs that are involved in the antagonistic components of the behavior – crucial for the development of sexual and adaptive behavior in the organisms. ANS plays a central role in the genesis of psychological and pathophysiological stress and control of animal behavior, by being intricately involved in the regulation of neuroendocrine balance, neuroeffector communication, and behavioral response of the individual. Sympathetic and parasympathetic activations are associated with release of specific hormones inside the brain and also from the peripheral endocrine

organs. Sympathetic nerves release adrenaline/epinephrine which has an activational role in fight-flight behavior and also increase heart rate acting at sinoatrial (SA) node; in contrast, parasympathetic nerves release acetylcholine which has calming effect and also decrease the heart rate.

Adrenaline/epinephrine is secreted from the adrenal medulla (which contains developmentally migrated sympathetic ganglions) in response to the neural stimulus reaching to it through sympathetic nerves. Both components of the ANS engage distinct sets of the hormones, neurotransmitters, and modulators to execute their effect. Hypothalamus is the master regulator of the ANS integrating the influences of all the contributory components and mechanisms.

**Gut Hormones: Influence on Behavior**

The hormones secreted in the gut (Table 1) not only have regulatory roles in feeding behavior, i.e., control hunger and appetite, but are also involved in maintaining mood and emotion, which has given rise to the concept of gut-brain axis. The gut-brain axis gets influenced by the common hormones (or hormone-like molecules) which are secreted in the gut as well as inside the brain – like peptide hormones (especially neuropeptide Y) and serotonin. The gut-brain axis is also influenced by the enteric nervous system (ENS) – which is predominantly autonomic in function. ENS in concert with the gut hormones helps to maintain the mood and emotion which will have a direct impact on the behavior of the organism – a dysregulation of gut hormone-ENS found implicated in many behavioral pathologies (Zhou and Foster 2015). Interestingly, human studies support influence of gut microbiota on behavior involving gut hormone-ENS (Skibicka and Dickson 2013).

**Hormonal Induction of Behavior: Underlying Mechanisms**

Animal behaviors range from simple reflexive actions like withdrawal of the limb when touched

with a prick or hot stick to a complex action like responding to the advances of a potential mate, the human-specific behaviors like playing a musical note, or responding to the offers of a business partner. Hormones have an influence on almost all aspects of animal behavior with the greater impact on that related to the species survival and proliferation like feeding and reproductive behavior and dealing with the threats to life and self-respect. (In Table 1 hormones implicated in various aspects of the animal behavior are indicated in superscript “c.”)

A hormonal influence on behavior depends on multiple factors, viz., age, sex, built, genetic makeup, developmental history, and early-life experience of the individual, also on the environmental context, duration of exposure to the stimuli, and associated rewards or threats. Hormone-driven behaviors such as sexual arousal and mate seeking, aggression to sexual opponent, response for food when hungry, etc. are conserved in animal kingdom and can be reproduced in the matching environmental and personal context (in contrast to the intellectually driven behaviors, which are specific to human and contain less hormonal influence and show more inter-individual variation).

A single hormone bears impact on many types of behaviors, or more appropriately a set of hormones together determine a particular behavior. A hormone’s final influence on behavior depends on the type and expression of the cognate receptors present on the target structures in the central and peripheral nervous system, which in turn depends on the encoding genes and their isoforms (Pfaff 1997; Maney 2017).

Hormones have two kinds of effect on the institution of behavior – “organizational” and “activational.” “Organizational” effect of the hormones is set during the development of the brain, and it determines the future response of the individual to the stimulus. In contrast, “activational” effect depends on the current status of the hormone in the body and determines immediate response.

Most of the hormones which are implicated in behavioral functions are either produced by neuronal tissue or by the components of central neuroendocrine axis regulating behavior – HPA/HPG

axis. In exception, some hormones – such as growth hormone (GH) secreted from anterior pituitary, thyroid hormones, and a newly known hormone Klotho, which is secreted from multiple animal organs (chiefly kidney, liver, skin) (Dubal et al. 2014), which are chiefly meant for somatic functions – have also been implicated in behavioral functions improving cognition (Table 1).

Hormone-behavior interaction is bidirectional, i.e., both can induce each other. The mutual dependency of the hormone and behavior provides conceptual basis for the behavioral corrections with therapeutic hormone manipulations and vice versa and hence constitutes a fundamental concept in the “behavioral endocrinology.”

### Genetic and Epigenetic Mechanisms

Hormone-driven behavior is hardwired in the genes and is seen grossly conserved across the animal kingdom. Any interindividual variation is attributed to the different gene isoforms for the hormones and their cognate receptors existing in the species population. Though, it is known to vary with the developmental history, early and current life experiences of the individual, which are not explained with any genetic theory. In recent years, a new concept “epigenetics” has been put forward to explain such lifetime variations in the hormone-driven behavior, which is defined as “a change in the DNA structure of an organism without introducing any change in its code sequence.” Such epigenetic changes in the DNA are environment induced and brought about by the chemical tagging of the DNA bases by methylation, or there can be changes in the DNA packaging material like histone proteins (methylation/acetylation) or in the methyl-binding proteins or through noncoding RNAs (micro-RNAs and long ncRNAs) (Cao 2014). Hormone-induced sexual differentiation of the developing brain and its impact on adult sexual behavior and also infant-mother interactions and other early-life experiences which may have grave impact on the future behavior as an adult are mediated through epigenetics. Though epigenetic mechanisms introduce environment-induced adaptive changes in the genomic structure of the organism, by a default mechanism, most of the epigenetic changes (gathered by an individual

either during embryonic development or through personal life experiences) do not carry forward in the offspring and get erased during gametogenesis (Hackett et al. 2013). Pertinent here is to mention that certain epigenetic changes as that created from severe chronic stress (involving HPA axis) may pass into next generations bypassing the default erasure – the phenomenon is called “trans-generational epigenetics” (Hackett et al. 2013; Jensen 2013). Epigenetics is considered to be instrumental in stress-induced alterations in HPA axis settings and their consequent effects on neurocognitive functions.

### **Institution of Social Behavior in a Newborn**

How social behavior is instituted in a newborn is not well understood. Supposedly, a newborn learns how to behave interacting with the environmental cues (although some of the newborn behaviors are innate and conserved – like crying just after birth, frequent startling, and exploratory behavior such as putting things in mouth). Empirical studies suggest that mother’s hormones in the breast milk bear impact on a newborn’s learning of the behavior (Grey et al. 2013). This observation has applied importance that any exogenous intake of hormones – like anabolic steroids – by the mother may be a hindrance to this learning. Excess glucocorticoids (mainly cortisol) released during stress in pregnant mother were found to have pathological impact on programming of HPA axis and consequent learning of behavior in fetus (Kinsella and Monk 2009).

### **Hormonal Disruption in Developing Fetus: Residual Effect on Adult Behavior**

Many chemicals released from artificial sources – industrial effluents and pesticides, heavy metals and plastics, and natural sources – derived from plant products, phytochemicals, when entered into the body as contamination, act as decoy ligands which hijack some components of the biological actions of the original hormones. Such chemicals are called hormone disruptors or endocrine-disrupting chemicals (EDCs) (Barrett and Patisaul 2017). Environmental estrogens and phytoestrogens are the prime hormone disruptors, known to affect neurocognitive domains in developing fetus, disrupting HPA/HPG (gonadal) axis,

in turn affecting institution of behavior. Loss of behavior will be noted not only for sexual and reproductive domain in affected fetus as adult, but normal intelligence and memory and social behavior may also get compromised.

### **Hormonal Correlates of Homosexual Behavior**

Homosexual behavior is known in human from archaic times and can be seen in many animals also. A scientific theory supporting the biological basis of homosexuality suggests that it has an in utero origin linked to prenatal overexposure of the fetus to an opposite sex hormone (Rice et al. 2012). Developing fetus faces a contrasting situation in utero, and maternal and fetal hormone levels adjust for the better survival of the fetus (Rice et al. 2012). Although both sex fetuses get exposed to both kinds of sex hormones normally, in certain cases, a sex hormone may dominate on others helping the survival, which may or may not be matched to the sex of the fetus. A contrasting exposure of a developing fetus to a sex hormone is proposed to influence its sexual behavior afterward as an adult, i.e., in utero exposure of a male fetus to estrogen-predominating environment may influence its sexual orientation in adult, and vice versa may be true for the testosterone exposure to a female fetus (Rice et al. 2012).

In an alternative view, a same sex hormonal predominance in the uterus for a pregnancy (necessitated for the survival of a particular sex fetus) may get tagged in the genome of the mother to get reactivated in subsequent pregnancies (through a phenomenon called epigenetics) and may influence in utero development of next opposite sex fetuses (Rice et al. 2012). A reversed 2D/4D ratio also was found predictive of homosexual behavior in the men (Xu and Zheng 2016).

### **Hormone-Induced Behaviors: A Brief Overview**

#### **Survival and Adaptive Behavior**

HPA axis hormones like CRH, ACTH, and cortisol and other hormones like arginine vasopressin – from posterior pituitary – and adrenalin/noradrenaline from adrenal gland are secreted in response to the acute and chronic stress (Table 8).

**Hormones and Behavior, Table 8** Hormones of stress

|                                                     |                    |
|-----------------------------------------------------|--------------------|
| CRH ↑                                               | Glucagon- ↑        |
| AVP ↑                                               | Insulin ↓          |
| ACTH ↑ glucocorticoids ↑ (cortisol, corticosterone) | Angiotensin- ↑     |
|                                                     | GnRH ↓             |
| Epinephrine ↑                                       | GH ↑               |
| Norepinephrine ↑                                    | Prolactin ↑↓       |
| Endorphin ↑                                         | Thyroid hormones ↓ |

HPA axis hormones are implicated in the mechanism of avoidance learning and escape – an adaptive behavior. Release of the stress hormones is associated with concomitant activation of the sympathetic system which adds up into the effect. Release of stress hormones in acute stress helps the organism to prepare for the flight or fight behavior (both of these bear survival values for the organism and constitute adaptive behavior). Conversely, the chronic exposure to the stress leads to abnormal forms of the behavior – like anxiety, panic, and depression – mediated by key molecular cascades like immediate early genes at synapses induced by persistently raised levels of the stress hormones (Senba and Ueyama 1997; Kozlovsky et al. 2008).

### Sexual and Reproductive Behavior

Sex hormones bear an exclusive influence on sexual orientation and drive of the animals including human. Both testosterone and estrogen are secreted in each sex, former being dominating in male and latter in female. Testosterone is convertible into secondary male hormones and also estrogen with the action of aromatic enzyme alpha-reductase in the brain and in periphery. Secondary male sex hormones are essential for the development of secondary sexual characters during puberty, and conversion of testosterone to estrogen by aromatization in medial preoptic nuclei of hypothalamus is obligatory for sexual motivation in males (Balthazart 2017). Different brain regions bear the receptors for sex hormones, especially that involved in maintaining neurocognition – the prefrontal and limbic cortex (including the hippocampus), hypothalamus, and amygdala (Blaustein 2004). Dimorphic sexual

behavior is regulated by sex hormones-directed modular gene expression in these brain regions. Various components of sexually dimorphic behaviors are governed by separable genetic programs, i.e., single genes control the specific components of the male/female sexual behavior (Xu et al. 2012).

Sex hormones induce an immediate sexual drive – while effects of testosterone are more robust and may induce aggression, the effects of estrogen are comparatively modest. Both hormones induce sex-specific behavioral and physical characteristics, as evidenced in diseases with sex hormone dysfunction and experimental studies in the animals. Male teens with androgen insensitivity syndrome in which dysfunction lies at the testosterone receptor have been shown to bear female-like physical and psychological characteristics, including sexual orientations and preferences. In contrast, in cases of in utero early testosterone exposure of a female fetus in a twin pregnancy (when another fetus is a male) or in case congenital adrenal hyperplasia (CAH) which may bring some masculine features in the female child and may also reflect in the behavior – showing characteristics of a male typical behavior. A sex-specific change of behavior also got noted in empirical studies involving animal models where either testis or ovary was castrated; conversely, the change of behavior got undone with reimplant of the removed gonad.

Sex hormones bear wider impact on interpersonal relationship involving opposite sexes. Cyclical change of the sex hormones in female are said to influence sexual behavior which might be reflected in interpersonal relationships. However, studies are lacking to support if same phenomenon is also occurring in the male. Though diurnal and periodic variations of the testosterone have been noted, corresponding changes in sexual behavior is not much defined in male animals, with exception of rabbits (in which a cyclical variation has been noted) (Degerman and Kihlström 1961). In male animals, alterations in sex hormone levels and accompanied sexual drive are limited by exposure to the female, freedom to intimacy, and engagement or abstinence from the sexual activities. Seasonal or annual surge of sex hormones is common in animals with exception

of the highest rank primates including human – in whom there is no such fixed pattern. The cyclic or periodic changes of sex hormones may be associated with sexual urge and fantasies and self-stimulating/gratifying practices. A periodic, seasonal, or annual surge in secretion of sex hormones is controlled by the releasing and stimulating hormones from hypothalamic and pituitary centers, respectively (Table 1).

Other than the sex hormones, posterior pituitary oxytocin and vasopressin are also noted to involve in sexual and reproductive behavior (discussed elsewhere in this chapter). Uniquely, an anterior pituitary hormone prolactin which is generally known to be associated with infant-parent bonding has also been found to be associated with the heterosexual pair bonding and its variation in secretion found to correlate with the amount of sexual behavior and contact affiliation in both sexes (Snowdon and Ziegler 2015).

### **Aggressive and Violent Behavior**

Empirical studies present evidence for causal association of testosterone in aggressive and violent behavior though a causal association has been challenged putting forward counter argument that aggressive/violent behavior is a by-product of testosterone's impact on individual's concern for gaining higher social status (Eisenegger et al. 2010). Sex violence by males has been almost exclusive and also correlated positively with serum testosterone levels (Studer et al. 2005). Testosterone is also found linked to incidences of aggressive behavior and violence by gun owners (Klinesmith et al. 2006).

### **Unethical Behavior**

Empirical studies have supported that a combination of the testosterone and cortisol may drive the subject into unethical behavior (Lee et al. 2015). Testosterone is said to influence a person's drive to acquire status-bearing resources (money, power, leadership, etc.) which gets further intensified by cortisol. Cortisol is released essentially in reaction to a stress and may be raised in a moral conflict leading to the mental strain, and it was found to associate with the reward-seeking and fear-reducing influence of the testosterone in studies (Lee et al. 2015). Individuals were found to

have lower serum levels of cortisol after committing unethical behavior as the commission of the act perhaps had given them a sense of relief from the mental strain (Lee et al. 2015).

### **Oxytocin: A Molecular Mediator of Positive Behavior and Bonding**

(Maternal behavior, sexual intimacy, romantic love, generosity, trust, ethical and spiritual behavior)

Oxytocin is the hormone in which most of the behavioral endocrinologists show particular interest. The physiological functions of oxytocin in breast milk ejection during child feeding, and its copious release during sexual intercourse and childbirth, are known since long. Oxytocin's role in maternal behavior is outstanding. A study noted induction of maternal behavior in virgin rats after intracerebroventricular injection of oxytocin (Pedersen et al. 1979).

Contemporary research has established its substantial role in intimate and positive aspects of behavior (Kosfeld et al. 2005; Insel 2010). In consecutive studies along the years, oxytocin has been strongly implicated in the peer bonding, romantic, and intimate relationship (Insel 2010), and many positive aspects of behavior such as trust, ethics, spirituality, and generosity (Kosfeld et al. 2005; Van Cappellen et al. 2016). A study implicated it in inducing an altruistic behavior in social groups against the ethnic backdrops (Marsh et al. 2017). Studies also implicated its determining role in the economic behaviors – such as in building the trust of the customers in the investors (Kosfeld et al. 2005).

Though having a substantial role in social behavior, all is not fascinating about this molecule. A study implicated it in some negative aspects of behavior as well, like doing a bias in favor of a social group to which individual belongs (Shalvi and De Dreu 2014). Further, an oxytocin-mediated behavior was found to be dose dependent and inducing at optimum serum/CSF concentrations only – violation of which may show contrasting behavioral effects, making its pharmacological exploitation for behavioral corrections difficult (Zhong et al. 2012; Bales et al. 2013). Furthermore, oxytocin is a biological mediator and facilitator of a positive behavior but cannot generate itself, which limits its

pharmacological use for this purpose. After all, expanded understanding of the oxytocin-mediated biological mechanisms has now brought the opportunity for the behavioral interventions aimed at inducing the positive behavior and bonding in various applied conditions.

### Personality Trait Association

Personality hormone association has not been a defined one, though unconfirmed descriptions of high testosterone and thyroid hormone association to certain personality traits being competitive, focused, and aggressive can be found in the literature. Plasma oxytocin level was found positively correlating with extravert behavior in studies (Bendix et al. 2015). Uniquely, an anthropological measurement comparing the length of the 2nd and 4th digits of the hands (2D/4D ratio), which is believed to reflect the prenatal testosterone/androgen exposure of the fetus, was found associated with sex-specific behavior as the adults (Galis et al. 2010; Xu and Zheng 2016). A lower 2D/4D ratio was found correlating with a more male typical behavior and vice versa was found true for a more female typical behavior. A mismatched prenatal exposure of the sex hormones have been associated with the borderline personality disorders.

### Pathological Behavior

Studies implicated hormones in the genesis of pathological behavior like gambling, drug addiction, and obsessive-compulsive disorders (OCD) such as compulsive stealing, binge eating, etc. HPA axis hormones are implicated in chronic stress-induced genesis of psychiatric disorders such as major depressive illness, bipolar disorder, schizophrenia, and PTSD (Kumar et al. 2017b). Chronic stress permanently alters the HPA axis regulation resulting in a persistently increased level of cortisol, creating basis for the pathogenesis of such psychiatric disorders by inducing the structure/function changes at synapses altering neural transmission and blunting the growth of the neuronal processes making connections in key brain regions involved in learning and memory – like hippocampus and prefrontal cortex. Behavioral effects of stress-induced cortisol are mediated by epigenetic changes at GR and involve MAPK signaling

pathway and Egr-1 (Revest et al. 2005). Another hormone, melatonin – which is known for maintaining circadian rhythm – was also found implicated in genesis of psychiatric disorders by various studies. Melatonin dysregulation perhaps plays by disrupting molecular clock in SCN of the hypothalamus and also the normal sleep pattern leading to detrimental changes in structure/function of hippocampus neurons, primarily suppressing continued neurogenesis which is crucial for learning and memory.

A persistently low serum level and diminished cortisol release response in acute stress challenge links with anhedonia – feeling no pleasure in normally pleasurable activities, depression, and suicidal behavior. A cortisol release response against presented acute stress challenge indicates how fervent or disheartened individual would respond to an eminent challenging situation. An optimum cortisol challenge response seems necessary for maintaining the healthy behavior.

Neuroplasticity induced by the hormones set the basis for the further neuroplasticity in future, a concept known as meta-neuroplasticity (Salma 2014). A dysregulation of the meta-neuroplasticity has been implicated in the progression of neurocognitive dysfunctions and also in the genesis of many neuropsychiatric diseases in adult where etiology has been developmental or early-life stress (Lai and Huang 2011).

## Introduction

Definitions of cognition generally refer to the ability of an organism to acquire, retain, process, and use information when required (Niemelä et al. 2013). Although these definitions are correct, they rarely capture the complexity involved in the

cognitive process or the role the endocrine system plays in driving cognition (Erlanger et al. 1999). The endocrine system is responsible for a plethora of functions from reproduction and growth to metabolism and stress but also has an effect on behavior, psychology, and cognition (Burdick 1938; Selye 1936, 1976). Of the more than 50 basic hormones produced by the 18 endocrine glands and specialized tissues, only a handful of these are responsible for exerting a direct or indirect effect on cognitive processes. Here, we discuss four of the most recognizable hormone groups that influence cognition: stress, reproductive, thyroid, and nonapeptide hormones. It should be noted that these are not the only, nor the most important, hormone groups that are able to influence cognition but they are easily recognized among the general public and researchers.

### Stress Hormones and Cognition

When faced with a possible homeostasis-altering stressor (natural/anthropogenic), the stress response of an organism is activated. Here, the sympathetic nervous system, the hypothalamic-pituitary-adrenal (HPA) axis, and the central neurotransmitter system are activated, all of which have effector mechanisms within the brain that play a role in information processing (Joëls and Baram 2009). The HPA axis, including the many affiliated endocrine glands and feedback loops, is responsible for the production and synthesis of corticosteroids (Sapolsky et al. 2000; Selye 1936). The secretion of these corticosteroids occurs in a pulsating and rhythmic fashion (Young et al. 2004). However, at any given time, the perception of a possible threatening situation, be it physical or physiological in nature, can result in a rapid increase of corticosteroid concentrations above the observed rhythmic peak (Groeneweg et al. 2012; Joëls and Baram 2009).

In this regard, the adrenal gland is responsible for the production and secretion of two important corticosteroids: glucocorticoids (GCs) and mineralocorticoids (MCs). In mammals, aldosterone is an important MC responsible for the control of extracellular fluid volume and blood pressure

(Joëls 2006). Cortisol and corticosterone, which are secreted in considerably higher amounts than aldosterone (~100 times), are GCs responsible for diverting energy supplies to the necessary organs while regulating cardiovascular and metabolic parameters (Reeder and Kramer 2005; Romero 2002). Despite the importance of both MCs and GCs in maintaining homeostasis, the role of corticosteroids in determining behavior and cognitive function (perception, attention, learning, and remembering; Wirth 2015) is often disregarded. The engagement of any cognitive process requires considerable amounts of energy, which is facilitated by the glucose metabolism function of GC (Erickson et al. 2003). And yet, GCs play a major role in both the consolidation and retrieval of information during the memory process. *Memory consolidation* refers to newly acquired information being converted from an unstable state (short-term memory) into a stable, long-term memory system (McGaugh 2000). *Memory retrieval* refers to the retrieval/remembering of already consolidated information (Souza-Talarico et al. 2011). This, however, is driven by the corticosteroid receptors present within the brain.

### Corticosteroid Receptors and Cognition

Both corticosteroid classes are produced by the adrenal cortex and secreted into the bloodstream before reaching the brain. Here their lipophilic nature results in the rapid movement of MC and GC across the blood-brain barrier (Sandi 2013). Despite their ability to enter the brain, the hormones are either (i) irreversibly degraded in the cytosol (Sandi 2004) or (ii) retained in cells where nuclear mineralocorticoid (MR) and glucocorticoid receptors (GRs) are present (Lu et al. 2006; Van Eekelen et al. 1988). In this regard, MRs are located primarily in the limbic system, with a preferential distribution in the hippocampus, amygdala, and motor cortex (Gass et al. 2000; Karst et al. 2010; Munier et al. 2012), while GRs are distributed in high densities throughout the prefrontal cortex and subcortical structures, including the hippocampus, amygdala, and hypothalamic paraventricular nucleus (Lupien et al. 2007). These regions of the brain have been shown to play an important role in cognitive,

emotional, and neuroendocrine control during the stress response (Joëls and Baram 2009; McGaugh 2004; Sánchez et al. 2000). Because MRs have a high affinity for corticosteroids, they are largely occupied even when stress hormone levels are low (de Kloet et al. 2005). In contrast to this, GRs have a tenfold lower affinity such that the receptors are only partially occupied at basal GC concentrations; and an increase in GC following a stressful event leads to an increase in occupation (Joëls and Baram 2009; Joëls et al. 2008). This allows for a mechanism whereby circulating GC can have different and/or opposing effects upon the hippocampus, depending on the concentrations present (basal vs. stressed; McEwen and Sapolsky 1995).

Both receptor types have been shown to exert slow, genomic actions, as well as rapid, non-genomic actions when binding to GC and MC. In terms of the former, GR activation following a stressful event ensures a delayed suppression of neuronal excitement and synaptic plasticity; this could assist in protecting information that is consolidated following a stress event (Joëls et al. 2007; Kim and Diamond 2002). Additionally, hormone-bound receptors translocate to the nucleus where they are responsible for regulating gene transcription, resulting in the generation of multiple isoforms of GR proteins via alternative RNA slicing (see Zhou and Cidlowski (2005) for a detailed review on GR). Each of these isoforms, and the possible receptor variances, accounts for a

range of unique biological responses such as development, growth, metabolism, and behavior (Sapolsky et al. 2000). During this process, it is the activation of MRs within the hippocampus that enables ongoing information processing.

In contrast to the receptors found within the brain, a number of localities outside of the brain also contain GRs and MRs, specifically the plasma membranes (Groeneweg et al. 2012). These receptors generally exert a rapid, non-genomic action by acting on steroid recognition sites at the plasma membrane (Groeneweg et al. 2012; Sandi 2004). When an imminent threat is perceived by an organism, the secretion of corticosteroids works to inhibit the HPA axis while promoting a rapid adaptive response. This response is largely behavior-based (“fight or flight”) but can also affect a number of cognitive processes (Roozendaal et al. 2010).

## Dose-Dependency

### Moderate GC Dose

The effect of GC on memory and information processing has been shown to be dose-dependent; this dependency has been defined as an *inverted U-shaped* relationship (Fig. 1) (Calabrese and Baldwin 2003; Joëls 2006). This dose-response relationship is primarily determined by the relative number and affinities of GR and MR within the brain (Wirth 2015). In order to achieve

## Hormones and

**Cognition, Fig. 1** The inverted U-shaped dose-dependent relationship between glucocorticoids and cognitive function, with moderate glucocorticoid concentrations showing optimal cognitive functioning

maximum long-term potentiation, and thus optimal memory consolidation, GC levels should be elevated enough to ensure that the majority of higher-affinity MRs are occupied by GC molecules, while an intermediate proportion of the lower-affinity GRs present within the brain are occupied (Joëls 2006; Wirth 2015). Thus, as MR-GC bindings reach optimal levels, MR-mediated effects such as hippocampal neurogenesis, neural excitability, and synaptic plasticity promote memory formation while maintaining integrity and plasticity in specific brain regions (Vogel et al. 2016). Furthermore, moderate GC concentrations have been shown to result in optimal receptor binding, translation, and electrophysiological functioning within the hippocampus which leads to long-term potentiation and primed burst potentiation (Schilling et al. 2013). The optimal MR/GR binding point is highlighted in the *GC Receptor Balance Hypothesis*; when the MR/GR ratio is high, i.e., GC concentrations are moderate with high occupation of MR but low GR occupation, memory performance is enhanced (Souza-Talarico et al. 2011). Specifically, moderate corticosteroid concentrations within the basal lateral amygdala, basal ganglia, and hippocampus facilitate memory processes (de Kloet et al. 1999; Erickson et al. 2003). An increase in GC and corticotropin-releasing hormone, a precursor of corticosteroids, in the hippocampus and amygdala promotes an increase in norepinephrine cell activity within the brain; this mechanism is known to enhance memory, especially when relating to fearful events (Butler et al. 1990).

#### Low and High GC Dose

In terms of the *inverted U-shaped* relationship between GC and cognitive function, considerably low or high GC concentrations are responsible for impaired cognitive capacities. The release of GC via the HPA axis is modulated according to the stress intensity experienced by an individual. Stress intensity is a term often used when describing the “strength” of the stress response to a perceived threat, as well as the time period over which the response is activated. As such, the intensity of the stress response experienced

by an organism is an important determinant of cognitive function (Sandi 2004, 2013).

If a perceived threat offers minimal danger to an individual (low-intensity stimuli), the production and secretion of GC into the bloodstream is limited, resulting in fewer binding events and, by extension, limited neuronal activation. This can lead to impaired information consolidation of both neutral and emotional information, as well as being detrimental to delayed memory consolidation (Lupien et al. 2002; Maheu et al. 2004). For example, Lupien et al. (2002) demonstrated that a reduction in circulating GC, which prevents the activation of the cortisol response in humans, resulted in a number of deleterious effects on delayed memory, specifically the retrieval of previously learned information.

Research over the last three decades has confirmed that chronically elevated GC can have a negative, deleterious effect on cognitive function. The activation of the stress response, and subsequent elevation in GC production over a prolonged period, will result in a high concentration of GC entering the brain. According to the *GC Receptor Balance Hypothesis*, during such periods of elevated GC, the MR/GR ratio is low and the occupation of MR and GR high; this level of occupation will result in cognitive impairment (de Kloet et al. 2000). This impairment has been observed in a number of different stages and types of memory processes, most notably *memory consolidation*, *retrieval of long-term memory*, *emotional memory consolidation*, and *working memory* (Wirth 2015). Such deleterious effects occur as a result of the atrophy in the apical dendrites of CA3 pyramidal neurons (Watanabe et al. 1992; Woolley et al. 1990), as well as increased apoptosis of newly generated neurons in the hippocampus, leading to a reduction in hippocampus plasticity and neurogenesis (McEwen 2000; Simon et al. 2005; Souza-Talarico et al. 2011).

The effect of low, moderate, and even high GC concentrations on cognitive function can be individual specific. Additionally, receptor densities within the brain not only differ between individuals (Champagne et al. 2008; McGowan et al. 2009) but can also fluctuate within an individual

over time (Pariante 2004). The receptor densities are largely determined by previous life experiences which determine GR gene expression, via methylation of DNA, over the long term (Wirth 2015). Interestingly, life experiences can influence GR gene expression, which determines receptor abundance within various regions of the brain, by modulating methylation of DNA over the long term. For example, higher infancy care in rodents results in less DNA methylation and greater receptor expression as adults, which impairs cognitive function at lower GC concentrations compared to adults that received less infant care and, thus, exhibit lower receptor expression (Champagne et al. 2008; Wirth 2015).

## Thyroid Hormones and Cognition

Thyroid hormones (THs), which include both triiodothyronine (T<sub>3</sub>) and tetraiodothyronine (T<sub>4</sub>), are important hormones that predominantly regulate metabolic pathways, through oxygen consumption, resulting in alterations in protein, lipid, carbohydrate, and vitamin metabolism (Smith et al. 2002). Though THs are also crucial for brain development, deficits of such hormones can result in permanent, deleterious, and profound effects on adult neurological function (see Zoeller et al. (2002) for a list of references (1–22)). The production of THs is driven by the hypothalamic-pituitary-thyroidal (HPT) axis in response to an energy-driven stimulus; the biologically inactive T<sub>4</sub> and to a lesser extent biologically active T<sub>3</sub> are produced by the thyroid follicular cells. However, the majority of T<sub>3</sub> is formed in peripheral tissues, such as the kidneys and liver, following deiodination of T<sub>4</sub> by the enzyme 5'-iodothyronine deiodinases type 1 and 2 (Bianco et al. 2002; Rivas and Naranjo 2007; Smith et al. 2002). However, when an individual's energy demands exceed its energy intake, T<sub>4</sub> conversion to T<sub>3</sub> is considerably decreased, thus lowering the concentration of available T<sub>3</sub> (Chatzitomaritis et al. 2017). Where food availability is not limited, T<sub>3</sub> concentrations are upregulated to meet energy demands during important periods such as molting, gonadal development,

pregnancy, somatic growth, and reproductive behaviors (Behringer et al. 2014; Gesquiere et al. 2018; Gobush et al. 2014).

## Thyroid Hormone Receptors and Cognition

Following their production and secretion into the bloodstream, both T<sub>3</sub> and T<sub>4</sub> bind to a variety of plasma proteins, with only a small percentage of T<sub>3</sub> and T<sub>4</sub> found in free form (Smith et al. 2002). Once THs reach their target organs (e.g., the brain), they enter the target cells through passive diffusion or a transport mechanism where further protein binding for intracellular transport occurs (Lazar 1993; Morte et al. 2010). Similar to GR and MR, thyroid hormone receptors (TR) are found throughout the central nervous system and brain, especially within the hippocampal area responsible for cognitive function (Bernal 2002). Here, TR are encoded by two genes, namely, TR $\alpha$  and TR $\beta$ , each of which has a number of isoforms (Lazar 1993; Rivas and Naranjo 2007). Following the binding of T<sub>3</sub> to TR within the brain, the expression of target genes by co-activators is activated. Both the TR and co-activators are responsible for a range of transcription modifications; as a result of this functionality, TH effects can be cell, tissue, and organ specific (see Cheng et al. 2010 for a review). Here, the TH are then responsible for accelerating the myelinating process while influencing cell migration, differentiation, and maturation. Additionally, TH control over the expression and transcription of various genes can regulate various forms of synaptic plasticity and memory formation (Rivas and Naranjo 2007). Although many of the TH actions are genomic in nature, they can also exert non-genomic, TR-independent activities by acting at the plasma membrane level; this includes the regulation of the ion channels and the activation of numerous signalling cascades (Davis et al. 2005).

## Dose-Dependency

Thyroid dysfunction, whether through trauma, disease, neoplasm, or hypo-/hyperthyroidism, and the resulting alterations in cell structure, function, and behavior, *have* shown the importance of THs in the development and maintenance of

neuronal systems and cognition (Erlanger et al. 1999; Smith et al. 2002). It is especially the alteration in hippocampal structure that is responsible for cognitive and behavioral deficits (Akaike et al. 1991; Alzoubi et al. 2009). In individuals with hypothyroidism, a decrease in T3 levels leads to a lower expression of certain genes, specifically positively regulated genes, while the expression of negatively regulated genes increases. The mechanisms involved in these effects of hypothyroidism include (i) the potential loss of T3 signaling and TR transactivations, as well as (ii) the intrinsic activity of unliganded TR, which are responsible for the repression of positive genes and the enhancement of negative genes (Gil-Ibañez et al. 2013) that lead to a reduction in neurite growth, synaptogenesis, and dendritic elaborations (Thompson and Potter 2000). As a result, deficits in attention, visual perception, executive function, memory, and emotions have been recorded (Grigorova and Sherwin 2012; Wahlin et al. 1998). However, the degree of deleterious effects of low T3 concentrations on cognitive function depends on the magnitude, duration, and timing of such a decrease. This has been highlighted in a number of studies which show contrasting results on the effect of low T3 concentration on cognition (Ritchie and Yeap 2015). Although hyperthyroidism can lead to a number of cognitive function deficits, this is usually to a lesser extent than observed in hypothyroidism. Similar to the latter, chronically elevated T3 levels will lead to impaired attention, memory, visuospatial abilities, and motor speed (see Bégin et al. 2008 – Table 5). In healthy humans, however, an increase in T3 levels led to no significant impairment of cognitive function and could even lead to improved verbal and visual processing (Kathmann et al. 1994; Münte et al. 2001).

## Reproductive Hormones

### Estrogen

Estrogens, a group of neuroactive steroid hormones, are primarily known as female reproductive hormones responsible for the development

of primary sexual characteristics and the induction of secondary sexual characteristics and eliciting pituitary response during pregnancy; while in males these hormones modulate libido, erectile functions, and spermatogenesis (Giese 2003; Schulster et al. 2016). Three endogenous forms of E are produced during various life stages; estrone (E1) primarily synthesized during menopause, the most prevalent and highly lipophilic form 17- $\beta$ -estradiol (E2), and estriol (E3) synthesized during pregnancy. Two types of E receptors (ER), ER $_{\alpha}$  and ER $_{\beta}$ , have been found in regions of the brain, particularly the hippocampus and amygdala, associated with memory, learning, and cognition (Gasbarri et al. 2012; Genazzani et al. 2000; Gundlah et al. 2000; Shughrue and Merchenthaler 2000). The abundance, tissue localization, and expression of ER demonstrate species-, intra-, and sex-specific differences (McEwen and Alves 1999; Muramatsu and Inoue 2000). Due to the general association of these regions with learning- and memory-related processes, E are believed to have modulatory effects on several neurotransmitter systems; in this regard the decrease in estrogen concentrations could increase the vulnerability of brain cells, particularly dendritic spine densities, to damage and degeneration (McEwen and Alves 1999; Woolley and McEwen 1994). Further studies found that, indeed, E can regulate neuroplasticity and neuronal excitability by both genomic and non-genomic pathways (Acconcia and Kumar 2006), in a time- and dose-dependent manner for a variety of mammalian models (Barha and Galea 2010). Additionally, E was found to have neuroprotective effects on the brain through transcriptional mechanisms that limit cell death (Hilton et al. 2004), as well as other receptor-mediated and non-receptor-mediated pathways (McCarthy 2008). A number of studies investigating gonadal hormone therapy, with particular applications in aging or memory-impaired individuals, found that E2 improves nonspatial memory of rats (Frick et al. 2002), initiated spatial learning and memory consolidation of meadow voles (Galea et al. 1995), and enhanced cognitive performance of *Rhesus Macaques* (*Macaca mulatta*, Hao et al. 2007). Though recent reviews

by Korol (2004) and Chisholm and Juraska (2013) suggest that several factors must be considered in determining the exact effect E has on cognition, some studies demonstrated that E impairs rather than improves cognitive performance (Fernandez and Frick 2004; Holmes et al. 2002), while another study found no significant effect during specific tasks (Galea et al. 2001).

### Testosterone

Testosterone (T), a steroid hormone from the androstane class, is secreted primarily by the Leydig cells of testicles in males. Testosterone is also secreted, though to a lesser extent, in the ovaries of females and the adrenal glands of both males and females (Appelgren 1969; Baird et al. 1969). Testosterone is predominantly responsible for the development of primary and secondary sexual characteristics, as well as a multitude of other peripheral functions (Bain 2007; Lee et al. 2009; Mooradian et al. 1987; Tuck and Francis 2009). Testosterone and its metabolites are also the primary determinants of both sexual and social behavior in male and female individuals, due to the interaction between peripheral and central actions of the hormones (Baucom et al. 1985; Pinna et al. 2005). Androgen receptors are not only found in brain regions crucial for learning and memory but may also modify the physiology and function of these regions by altering the synaptic density of the neurons (Janowsky 2006). However, there are multiple T mechanisms, such as T aromatization or neuronal biosynthesis from endogenous cholesterol, that make it difficult to discern the mechanism of action that leads to the enhancement of neural tissue and, by extension, the improvement of cognitive performance (Mukai et al. 2006; Naghdi et al. 2001; Roselli et al. 2009) (Davey and Grossmann 2016; Frye et al. 2001; Sak and Everaus 2004). Testosterone-related enhancement of cognitive functioning appears to be age-specific, sexually dimorphic, and dose-dependent (Goudsmit et al. 1990; Roof 1992; Spritzer et al. 2011), though androgen administration to specific regions of the brain also determines whether learning and memory performance is enhanced or impaired (Edinger and Frye 2004).

### Progesterone

Progesterone (P) and its neurosteroid derivative, allopregnanolone (AP), are primarily secreted by the ovaries and the placenta during pregnancy and synthesized in smaller amounts by the adrenal glands in both males and females (Barros et al. 2015). There are also mechanisms that exist within the central nervous system, neurons and glia, with the ability to biosynthesize AP and a neurotransmitter-type derivative, neuroprogesterone (Chabbert-Buffet et al. 2000; Schumacher et al. 2001, 2014; Sripada et al. 2013). Two isoforms of P receptors, P<sub>A</sub> and P<sub>B</sub>, are co-expressed in most tissues and widely distributed in various regions of the brain responsible for memory consolidation and learning, though some are exclusively estrogen-inducible (Alves et al. 2000; Schumacher et al. 2014). The majority of studies that investigated the neuroprotective effects of administered P or synthesized derivatives on cognitive performance to date have used animal models that are aged, have undergone gonadectomy, or mimic certain cognitive dysfunctions or age-related neurodegeneration diseases (Singh and Su 2013). Though P has generally preserved cognitive performance in such compromised cases (Cutler et al. 2007), a few studies have shown no effect (Chesler and Juraska 2000), or even a negative effect on cognitive performance/processes, such as long-term potentiation (Foy et al. 2008). Although the general consensus varies, many studies concur that P and AP differentially enhance cognition depending on age (Lewis et al. 2008), the timing of the treatment (Harburger et al. 2008), and the type of progestin and dosage administered (Djebaili et al. 2004). In addition, combined administration of both estrogen and progesterone may improve cognitive performance differentially in aged females (Gibbs 2000), which has shown to be dependent on menstrual cycling in females (Kromrey et al. 2015).

### Nonapeptide Hormones

Two related nonapeptide hormones with unrelated functions, oxytocin (OT) and vasopressin (VP), may influence cognitive function, memory

formation, and even protection against age-related impairments in rodents and nonhuman primates (NHPs). Oxytocin and arginine vasopressin (AVP), the common mammalian form with the exception of *Suinae*, are synthesized predominantly in magnocellular neurons of the paraventricular and supraoptic nuclei of the hypothalamus, respectively, and extend to the posterior pituitary gland or to sites within the central nervous system (Buijs 1990; Insel 1992; Lee et al. 2009; Swaab et al. 1975). The general peripheral functions of OT include reproductive effects such as uterine contractions, penile erections, and other facilitative effects on sexual behavior, as well as effects on social behaviors such as grooming, maternal care, pair-bonding, and others (Argiolas and Gessa 1991; Burbach et al. 2006; Insel and Shapiro 1992; Jarcho et al. 2011).

### Oxytocin

Oxytocin has been previously described as a neurotransmitter within the brain that has the potential to influence neuronal excitability (Buijs 1983; Kovacs and Telegdy 1982), with priming abilities that rewire neural networks to influence behavior (Ludwig and Leng 2006). Early evidence of this was determined by the presence of an OT receptor and OT receptor mRNA expression within various regions of mammalian brains involved with memory consolidation, learning, and social cognition (Baribeau and Anagnostou 2015; Chang et al. 2013; Gimpl and Fahrenholz 2001; Yoshimura et al. 1993). The localization of OT receptors, and by extension the levels of OT, throughout the brain shows species-, intra-, and sex-specific differences in distribution and concentrations; this can be influenced by species-specific social organization or structure (Beery et al. 2008; Insel and Shapiro 1992; Rosenblum 2002) and is susceptible to change throughout development and aging (Arsenijevic et al. 1995; Tribollet et al. 1992; Yoshimura et al. 1993). A plethora of studies have investigated the effects of OT within the brain of primates and humans, and these studies demonstrated that OT is important for the acquisition of social memory and maternal memory consolidation (D'cunha et al.

2011; Ferguson et al. 2002) especially in cases where OT levels were significantly low, resulting in social memory deficits (Ferguson et al. 2000). However, some results seem to indicate that OT may selectively facilitate social cognition rather than act universally (Bartz et al. 2010; Heinrichs and Domes 2008).

### Vasopressin

Though VP principally acts as an antidiuretic hormone within the kidneys, AVP is also responsible for vasoconstriction and blood pressure regulation in peripheral tissues and acts synergistically with corticotropin-releasing hormone to regulate pituitary adrenocorticotrophic hormone secretion during stress (de Bree and Burbach 1998; Ma and Lightman 1998; Robertson 2001; Strupp 1984). Arginine vasopressin receptors are separated into three groups according to the intracellular mechanisms employed: V1a and V1b and V2 (Egashira et al. 2009; Hammock et al. 2005). The type, distribution, and abundance of AVP receptors within various regions of mammalian brains differ between species, within species and individuals, and are often sexually dimorphic (Hammock et al. 2005; Young et al. 1999). Prefatory studies in the 1970s and early 1980s tested AVP's effects on memory consolidation and retrieval; the results suggested that AVP and its analogs may have the ability to prevent or reverse amnesia (van Wimersma Greidanus et al. 1983). With particular interest in aging or aged individuals, AVP, its analogs, and to a lesser extent lysine vasopressin have been found to improve cognitive performance, enhance learning and memory behavior, and prevent memory function deficits caused by neurotoxic peptide-induced loss of memory (Bartus et al. 1982; Buresova and Skopkova 1982; Jing et al. 2009; Pan et al. 2010).

## Hormones and Face Preferences

Mercedes Hughes

Oakland University, Rochester, MI, USA

### Introduction

Preferences for a particular face are unique and personal; however, there are overall trends in what men and women find attractive in a face and their preference for any given face to look more masculine or feminine. Face shape, facial coloration, brow ridge, cheekbone placement, and jaw line all contribute to the overall look of a face and whether that face is perceived as masculine, feminine, and attractive in general. A masculine face is typically characterized by a more prominent nose and brow ridge, as well as a wider and more angular chin or jaw line. Conversely, a feminine face has a softer brow ridge and more rounded jaw line. Changes to these aspects of the face effect whether the face is perceived as masculine or feminine. While these preferences are personal, both men and women exhibit changes in facial preferences associated with changes in hormone levels. These preferences change for women during the natural menstrual cycle and for men with fluctuations in testosterone as well as with the woman's changing hormonal profile.

### Theoretical Background

The face preferences of women and men change during the menstrual cycle and with fluctuating hormone levels (e.g., Jones et al. 2008; Penton-Voak et al. 1999; Penton-Voak and Perrett 2000; Puts et al. 2013; Roberts et al. 2004; Welling et al. 2007). These preferences may shift towards more masculine or feminine facial characteristics or be exhibited as more attraction during a particular phase. While it is known that these face preferences change across the menstrual cycle, the exact mechanisms and reasons for these shifts are

unknown. However, several theories predict possible preference shifts. For women, one such theory predicts that during ovulation, when fertility and likelihood of conception is highest, women may show increased attraction to male faces that exhibit cues to heritable immunity to disease (Folstad and Karter 1992). The theory suggests that women should show a preference for male features that signal her offspring could inherit the benefits of immunocompetence. However, these benefits can only be gained if conception occurs following copulation. Therefore it is expected that women should show a preference for immunological competence when conception is most likely, during the follicular phase. (Gangestad and Simpson 2000; Gangestad et al. 2004; Thornhill and Gangestad 2008). This theory would then predict an increased attraction to masculine facial features during the follicular phase of the menstrual cycle. Indeed, masculine traits and ratings of men's facial masculinity are positively associated with estimates of good health and signal indirect benefits to the woman of heritable immunological competence for her offspring (e.g., Gangestad et al. 2004; Johnston et al. 2001; Penton-Voak et al. 1999; Penton-Voak and Perrett 2000). However, the masculine features associated with immunocompetence are also associated with increased testosterone levels and dominance. While a preference for a masculine face might confer indirect benefits during high fertility, it may also be costly due to decreased paternal investment. Less masculine faces confer direct benefits of paternal investment and familial support. Therefore, there exists a tradeoff between good genes conferred through masculine facial preferences and high parental investment for more feminine faces (Gangestad and Simpson 2000). Due to this tradeoff, it would benefit women most to modulate their mate facial preferences depending on likelihood of conception (Fink and Penton-Voak 2002; Gangestad and Simpson 2000). When conception is not likely and the body is preparing for pregnancy, such as during the luteal phase of the menstrual cycle, women may then exhibit a stronger preference for more feminized faces that characterize benefits such as material support and parental investment.

Consequently, the theory suggests that changes in facial preferences across the menstrual cycle might be due to a mixed mating strategy whereby a female might choose a primary partner with low facial masculinity for direct benefits of paternal care, but then may also copulate with males with high facial masculinity when most fertile for indirect benefits of immunocompetence (Folstad and Karter 1992). For males, changes in facial preferences across the female menstrual cycle more likely have to do with gaining a competitive advantage. Unlike other mammals, ovulation in human females is not readily obvious. Cues to fertility and ovulation are largely hidden, which creates an adaptive issue for males (Thornhill and Gangestad 2008). Therefore, the males that are able to detect subtle cues to ovulation would have a significant advantage in being able to mate with the fertile females (Puts et al. 2013). It would be beneficial, then, for males to exhibit a preference for female faces when they are in the fertile phase or near ovulation so that they can focus their mating efforts. These theories may help to explain the current findings on why men and women experience facial preference shifts.

### Female Face Preferences and Hormones

During a woman's menstrual cycle, there are fluctuations in hormones that dictate fertility. Across the normal menstrual cycle (i.e., no hormonal contraceptives), a woman's preferences for a masculine or feminine faces change. The cycle can be split into the follicular, luteal, and menstrual phases. During the follicular or fertile phase, estradiol levels begin low and steadily increase, peaking just prior to ovulation. Progesterone levels are low in this phase and remain steady until ovulation has occurred. When ovulation occurs, estradiol levels temporarily decrease. During the luteal phase, the corpus luteum forms at the site of ovulation and causes estradiol and progesterone to increase and peak mid-phase before sharply decreasing just prior to menstruation if pregnancy has not occurred. If fertilization and implantation do not occur, the uterus sheds its lining and menstruation occurs.

During the follicular or fertile phase of their menstrual cycle, women are more likely to prefer and choose a face with more masculine features compared to other phases of the cycle (e.g., Johnston et al. 2001; Jones et al. 2008; Penton-Voak et al. 1999; Penton-Voak and Perrett 2000; Welling et al. 2007). This finding is in line with the theory that predicts women should prefer more masculine faces when conception is most likely. The exaggerated masculine features indicate higher testosterone and are associated with characteristics that signal immunological benefit to offspring when conception is most likely (e.g., Folstad and Karter 1992; Gangestad and Simpson 2000). However, when conception is not likely, this effect is not seen. During the luteal phase or menstrual phase when fertility is low, women prefer more feminized male faces (Johnston et al. 2001; Jones et al. 2008; Perrett et al. 1998). The feminized male faces are positively associated with personality attributions such as being perceived as more cooperative and a good parent, and these attributions correlate with actual behaviors (Berry and Wero 1993). Additionally, face preferences can change when the face is being judged as attractive for a long-term versus short-term relationship. When conception risk is high (i.e., follicular phase or near ovulation), masculine faces are preferred for short-term relationships. However, when women judge attractiveness for long-term relationships, preferences remained constant preferring more feminized faces. These cyclic changes in preferences are absent in hormonal contraceptive users, whose fertility is not changed with the menstrual cycle (Folstad and Karter 1992). Yet conception risk cannot be the mechanism for the change in facial preferences. There must be a hormonal mechanism driving the change in behavior and preferences across the menstrual cycle. Indeed, lower progesterone levels, such as during the follicular phase of the menstrual cycle, are associated with preferences for more masculine faces (Jones et al. 2005a, b). Conversely, estrogen levels alone are not associated with preference changes across the menstrual cycle (Puts 2006; Jones et al. 2005a, b). The change in progesterone level seems to be an important mechanism for the change in face

preferences, yet it is not the only hormonal mechanism at work. Like progesterone levels, testosterone levels fluctuate during the menstrual cycle. Testosterone levels start off relatively low following menstruation then slowly increase and peak near ovulation before steadily declining again. When women's testosterone levels are highest around ovulation, they show the strongest preference for masculine faces (Welling et al. 2007). Importantly, this behavior change associated with testosterone level is independent of progesterone or estrogen levels. This suggests that both progesterone and testosterone are involved in the mechanism for preference changes across the menstrual cycle.

It is not just changes in preferences for attraction that fluctuate during the menstrual cycle. Preferences for facial resemblance to self also vary across the menstrual cycle. Facial resemblance or other facial cues of kinship can signal direct benefits such as support from family when raising children. However, these same cues can signal decreased indirect benefits such as inbreeding and less genetic variability for the offspring (DeBruine et al. 2008). These may be some of the reasons contributing to the preference changes for facial resemblance seen in women during the menstrual cycle. Women show a greater preference for self-resembling faces when they are in the luteal phase, when fertility and conception risk are low. This preference for self-resembling faces is not present during the fertile follicular phase (DeBruine et al. 2005). The preference for self-resemblance is positively associated with progesterone levels, which suggests that women may increase their preference for kinship cues when the body is preparing for pregnancy and they might need familial support the most.

Similarly, facial cues to health can vary across the menstrual cycle. Women show a greater aversion to faces that signal poor health and illness (e.g., pallor) during the luteal phase when progesterone level is high and the body is preparing for pregnancy (Jones et al. 2005a, b). This effect is particularly pronounced when women are judging male faces on attractiveness for short-term relationships. The change in attraction to faces with cues to high or low health is associated with the

change in progesterone level. This again suggests that women may have a preference for faces with cues to good health when the body is preparing for pregnancy and the cost of becoming ill is high.

## Male Face Preferences for Females

Women are not the only ones who experience facial preference shifts during the menstrual cycle. Men too show preference shifts during the female menstrual cycle and with their own fluctuating hormone levels (e.g., Probst et al. 2016; Puts et al. 2013; Roberts et al. 2004; Welling et al. 2008). While women experience those shifts due to their own changing hormone profiles, men do not have a monthly cyclic change in hormone levels. Therefore, the mechanism by which men's facial preferences change is both indirect through the female's changing hormones and direct through their own. In many nonhuman mammals, when the female is fertile near ovulation, she will show changes in appearance, smell, and behavior (Gangestad and Thornhill 2008). These changes signal to the male that the female is most fertile and receptive, and in turn the male makes behavioral changes to increase mating efforts. If ovulation was readily apparent in humans, this could explain the male shift in facial preferences. However, in humans, cues of ovulation are not so obvious or able to be consciously perceived. Yet, subtle changes in facial shape or color may be detectable subconsciously. Indeed, when men view photographs of women's faces in the fertile window versus the luteal phase, they judge the women in the fertile phase as more attractive (Puts et al. 2013; Roberts et al. 2004; Welling et al. 2007). Additionally, when the face shape characteristics of different cycle phases are isolated and made into average composites for either the follicular or the luteal phase, men again rate women's faces associated with follicular phase as more attractive (Bobst and Lobmaier 2012). The subtle face shape changes are theorized to be due to changes in progesterone. Indeed, the changes in progesterone are negatively associated with facial attractiveness ratings (e.g., Puts et al. 2013; Roberts et al. 2004).

In other words, men rate women's faces as more attractive when progesterone is low, such as during the follicular phase. Estradiol alone does not show these same effects, likely because it does not differ significantly between the late follicular and luteal phases. However, the ratio of women's testosterone-to-estradiol ratio does play a role. Men rate women with a low testosterone-to-estradiol ratio and low testosterone as having more attractive faces (Probst et al. 2016). These indirect mechanisms of preference shifts are dependent upon the female's changing hormones. However, men's own testosterone levels can affect their facial preferences as well. Much like women, testosterone also plays a role in changing face preferences. When men's salivary testosterone is relatively high, they judge attractiveness of women's faces that have been feminized as more attractive. In other words, they are more attracted to femininity when their testosterone levels are high compared to when they are low (Welling et al. 2008).

## Conclusions

Both women and men experience shifts in their facial preferences. For women, the mechanism by which these shifts happen is more direct and linked to her changing hormones during the menstrual cycle. For men, these shifting preferences can be both direct through their own changing hormone levels, or indirect and dependent on the woman's hormonal shifts. Overall, women show a preference for more masculine faces when they are in the fertile phase and near ovulation compared to other phases of the menstrual cycle. During the fertile phase, progesterone levels are low and testosterone levels are at their peak. Conversely, in their non-fertile phases, when progesterone levels are high and testosterone levels are low, women exhibit preferences for faces that are more feminized. The exact reason for these preference shifts across the menstrual cycle is not known; however, several theories support these findings. One possible theory is that women show increased attraction to masculine faces near ovulation because masculine faces signal heritable

immunity to disease. This preference may happen during ovulation because it is when conception risk is highest. When conception is not likely, such as during non-fertile phases, women should show a preference for more feminized faces which are associated with greater parental investment. This type of dual mating strategy would allow the woman to choose a primary partner with a more feminized face associated with good parental investment, but occasionally choose to mate with more masculine faced men during times when conception is likely to confer indirect benefits of good genes and health to her offspring. Men show a preference for women who are in the fertile phase of the menstrual cycle over those who are in non-fertile phases. This corresponds to a preference for low levels of progesterone and a low testosterone-to-estradiol ratio. Additionally, men are most attracted to femininity of faces when their own testosterone levels are highest. These preference shifts are likely due to an adaptive advantage for men to pick up on subtle cues of fertility. Males who are able to detect fertile females then have the advantage of focusing their mating efforts towards only females likely to conceive and thus pass along the male's genetic information.

### Definition

The sport, recreation, or activities in riding horses.

### Introduction

Horses have been an integral part of human history and progress in diverse ways throughout history. A popular pastime between humans and horses is horseback riding. A variety of activities and lifestyles are used in horseback riding, and riders are trained in various disciplines and styles of riding. Each type of horseback riding incorporates unique skills and equipment for pleasure, sport, and recreation. The two main styles of horseback riding are English and Western. Each style of riding includes diverse activities for riders, which are used for competitions and pleasure. In addition to English and Western style, horseback riding also includes racing, rodeo, trail riding, vaulting, and therapeutic riding.

## English Style

English horseback riding has endured throughout history and includes several diverse activities and competitions. Although most English style riding activities consist of the use of a flat saddle and reins are controlled by both hands, each English riding activity has a unique style, purpose, and trained skills. Horseback riding consisting of English style activities includes dressage, show jumping, hunter jumping, eventing, and polo, as well as flat class competitions (Driscoll 2019; Extension Campus 2019).

Dressage, which is noted as a classical form of training and horseback riding, can be traced back to the ancient Greeks of the fourth century BC, although its French name was not coined until the eighteenth century (Crossley 1987). The word *dressage* is derived from the French verb *dresser*, which means to train or adjust (Crossley 1987). The purpose of modern dressage competitions is to evaluate the horse's training, which increases in difficulty with the progression of training (Extension Campus 2019). The areas of evaluation in dressage competitions include the horse's obedience and harmony with the rider, transitions between movements, precision, and smoothness while completing a prescribed pattern of movements (Extension Campus 2019). Dressage is also a popular event in the Olympics and is compared to ballet as the horse is performing to a series of movements choreographed to music (Driscoll 2019).

Show jumping is a popular competitive equestrian sport. The earliest historical descriptions of show jumping can be traced back to the eighteenth-century French cavalry (Smith 1987), which influenced international popularity and competition. In show jumping events, the horses are specifically trained to jump large jumps within a specific time limit without knocking down the jumps or refusing to make the jumps (Extension Campus 2019). If all of the horses in the competition successfully complete all of the jumps, the horse with the fastest time will be declared the winner (Extension Campus 2019). Show jumping is also a popular event in the Olympics.

Hunter jumping is one of the earliest forms of horseback riding, which has a rich history in England as part of fox hunting, and it is considered a tradition in British culture (Clayton 1987). The role of the horse in early hunter jumper competitions was to be able to gallop and jump fences and ditches without hesitation in pursuit of the fox (Clayton 1987). Hunter jumping has also been combined with racing activities in which racecourses are designed like riding in a country setting and includes streams, fallen logs, and other natural elements which the horses are required to jump (Driscoll 2019). In most hunter jumper competitions, hunters are judged on manners, quality and ease of gaits, and safety over fences (Extension Campus 2019).

Eventing is an equestrian triathlon competition, which can trace its development to the training of military horses (Extension Campus 2019). This type of horseback riding competition includes elements of dressage, show jumping, and the speed and endurance of hunter jumping (Pontifex 1987). Eventing is a rigorous form of horseback riding and competition that tests the abilities and athleticism of the horse and rider, and it is also a popular event in the Olympics.

Polo is a horseback riding activity that originated in China more than 2000 years ago (Macgregor-Morris 1987). Polo gained in popularity in India and England before becoming an international sport and competition (Macgregor-Morris 1987). In the game of polo, four-person teams of horses and riders use a stick called a mallet to hit a ball through goal posts for a period of 7 min known as a chukker (Extension Campus 2019). Polo is a fast moving sport, and most polo players ride different horses for each chukker played in a competition (Extension Campus 2019).

Flat class horseback riding is an English activity that does not include jumping. Flat class competitions include walking and trotting, and horses are evaluated on their manners and responsiveness to the rider, as well as the quality of their gaits (Extension Campus 2019). This type of horseback riding is popular because it includes many different types of riders and horses of diverse breeds, skills, and abilities.

## Racing

Racing horses was also a part of the rich history of Ancient Greece, and it was included as an Olympic event (Driscoll 2019). Although most cultures engaged their horses in racing, it was England who introduced Thoroughbreds to the sport, and it became a popular pastime for the aristocracy (Driscoll 2019). The Thoroughbred was developed through selective breeding in seventeenth-century England, but modern Thoroughbred breeding and racing is an international industry (Condry 1987).

The first official Thoroughbred race in the United States took place in 1873 in Saratoga Springs, New York, but racing became more popular in Kentucky, host of the famous Kentucky Derby at Churchill Downs, which was established in 1883 (Driscoll 2019).

The equipment used in horse racing is similar to other English riding activities. Racing saddles are very lightweight, and the riders, known as jockeys, must also maintain a certain weight so that the horse's speed is not inhibited by excess weight.

## Western Style

Western style riding is commonly thought of as the "cowboy" way, but this type of horseback riding also includes many diverse activities. Unlike English riding saddles, Western saddles are larger and heavier, and many saddles also have a horn on the front for various riding activities. Unlike English style in which riders use reins in both hands, Western style riders typically use reins in one hand to accomplish skills and tasks (Driscoll 2019). Western horseback riding includes western pleasure, reining, and team penning (Extension Campus 2019). Other Western horseback riding activities may also include steer or calf roping, as well as other rodeo activities, such as barrel racing or pole racing (Driscoll 2019).

Western pleasure horseback riding is judged on the horse's ability to perform required gaits of riding, such as a walk or a jog, in a quiet and enjoyable manner (Extension Campus 2019).

Reining and team penning are popular Western horseback riding activities that can also be included in rodeo activities. Reining competitions evaluate the horse's response as controlled by the rider while performing a set pattern that includes various skills such as spinning turns and sliding stops (Extension Campus 2019). Team penning is a timed competition in which a team of horseback riders must separate specific cattle from a herd and hold them in a penned area (Extension Campus 2019).

Roping events, such as steer or calf roping, exhibits the horse's ability to track a running calf or steer, allowing the rider to lasso the animal and temporarily restrain it (Extension Campus 2019). In competitions, the team that most quickly ropes the animal, dismounts, and ties three of the animal's legs together, wins the event (Extension Campus 2019).

## Rodeo

Rodeo is a competitive type of Western horseback riding that includes several events and activities, which is based on skills that cowboys need to perform their jobs on the range and large ranches. Popular rodeo activities, such as bareback or saddle bronc riding in which the rider tries to stay on a bull for 8 s and calf roping to catch animals for branding, are often included in rodeos (Extension Campus 2019). Barrel racing demonstrates the speed and quickness of horses as they race around barrels placed at opposite ends of the arena in a cloverleaf pattern (Extension Campus 2019). Pole bending is a horseback riding competition in which the rider must weave the horse in and out of six tightly spaced poles. Although it was originally known as a "cowboy" style of riding, the rodeo is a popular international event, and it officially became part of the Olympics in 2002 (Driscoll 2019).

## Trail Riding

Trail riding is one of the most popular disciplines in horseback riding, which is open to all riders and breeds of horses, as well as a way to connect with

nature and other horse enthusiasts (Extension Campus 2019). Additionally, trail riding is a non-competitive, recreational activity that can include English or Western equipment and styles of riding (Driscoll 2019). In trail riding competitions, the test includes the horse's ability to safely, calmly, and willingly negotiate obstacles normally encountered on a trail, which may include walking over a bridge or opening and closing a gate (Extension Campus 2019).

## Vaulting

Vaulting is an activity in which riders perform movements on and around the horse (PATH Intl 2019). The activities included in this type of horseback riding are similar to movements in gymnastics and dance and are performed in harmony with the horse (Extension Campus 2019). Interactive vaulting can also be a part of therapeutic riding, as it fosters teamwork, independence, and confidence, as well as introducing all gaits of riding in a short period of time (PATH Intl 2019).

## Therapeutic Riding

Historical sources also suggest that horses were viewed as healing or therapeutic for humans since the time of the early Greeks (Hallberg 2018; Battestella-Williams 2019). References to the healing and recovery processes using horses can be found in writings from ancient Greco-Roman times (Bachi et al. 2011; Battestella-Williams 2019), including Hippocrates, who believed that horseback riding provided a healing rhythm (Hallberg 2018) because it moves the body in a similar manner to a human gait, which helps improvement in balance, flexibility, and muscle strength (PATH Intl 2019). Lis Hartel, who was paralyzed from the knees down after contracting polio, is often considered the pioneer of therapeutic horseback riding (Hallberg 2018; Battestella-Williams 2019). Hartel won the silver medal for Denmark in the 1952 Helsinki Olympics (Bachi et al. 2011; Hallberg 2018; Battestella-Williams 2019). Shortly afterward, Hartel formed the first

therapeutic riding center in Europe for people with disabilities (Hallberg 2018; Battestella-Williams 2019). During the 1950s and 1960s, other rehabilitative riding programs were formed throughout the United Kingdom, the Netherlands, and Belgium (Hallberg 2018). Today, therapeutic horseback riding is used for diverse physical, physiological, and neurological symptoms. This type of horseback riding is typically known as *adaptive riding*, which refers to a nontherapy type of equine-assisted activity that includes horseback riding and horsemanship skills to students with disabilities or special needs and is sometimes used synonymously with the term “therapeutic riding,” (Hallberg 2018; Battestella-Williams 2019). Therapeutic riding is an activity working with horses with the purpose of contributing positively to the cognitive, physical, emotional, and social needs of individuals with special needs (PATH Intl 2019).

## Conclusion

Horseback riding is a very diverse recreational activity that many different levels and types of riders can enjoy. Additionally, there are many other types of activities that include horseback riding, such as vacations at dude ranches and various types of shows and attractions that feature horses.

## Definition

An attractive potential mate that garners both male and female attention which received a disproportionate percentage of copulations in a mating season.

## Description

While many species engage in mating rituals that advertise territory quality, parental care, or other tangible resources, several species engage in lek polygyny, whereby male animals aggregate on an arena or “stage” to engage in competitive displays (i.e., lekking) with the ultimate goal of securing female mates (Fiske et al. 1998). Most lekking species are birds (e.g., grouse, ruff, manakins, birds-of-paradise), although some mammals (e.g., waterbuck, some pinnipeds, and the topi), amphibians (e.g., bullfrogs), reptiles (e.g., marine iguanas), fish (e.g., cichlids), and insects (e.g., midge, ghost moth) also engage in lekking (Fiske et al. 1998).

Lekking represents a paradox because in lekking species, typically only one or a few males are successful at garnering a mate. Thus, if persistent female mate choice for particular traits exists, how can genetic diversity in lekking species be maintained, and how can choice of mates persists (Miller and Moore 2007)? In other words, how could lekking have evolved?

One hypothesis is the hotshot hypothesis (Beehler and Foster 1988). Unlike the female preference model (Bradbury 1981) or the hotspot model (Bradbury and Gibson 1983), the hotshot model is the only hypothesis attributing males as the driving force behind lekking behavior. According to this hypothesis, attractive males (hotshots) attract females via behavioral or morphological attributes. Other, less successful males cluster near the hotshots and are able to obtain more matings than they otherwise would had they displayed alone (Beehler and Foster 1988). According to the hotshot hypothesis, four factors can promote the development of a lek mating system: (1) male-male competition for dominance, (2) an initial inequality of mating success among males, (3) simple and conservative female mating patterns, and (4) secondary male reproductive strategies. Thus, the hotshot hypothesis downplays the importance of female mate choice based on male traits (contrary to the female preference model by Bradbury et al. 1985), and emphasizes the importance of male social dominance.

Experimental evidence supports the hotshot hypothesis. Jiguet and Bretagnolle (2006) manipulated little bustard leks using decoys to alter sex ratio and male phenotype. They found that hotshot males exist in this species (the decoys attracted both wild females and males) though they also found evidence for the female preference hypothesis (females preferred a particular lek size). Thus, hypotheses for the evolution of the lek mating system may not be mutually exclusive.

## Synonyms

Biodiversity hotspot

## Definition

A hotspot is a region which has at least 1,500 endemic vascular plants (>0.5% of the world's total) and has 30% or less of its historical habitat remaining.

## Introduction

The combination of anthropogenic activity and climate change threatens biodiversity (da Fonseca et al. 2007). Conservation of biodiversity is necessary to supply ecosystem services and to support their health and resilience (Millennium Ecosystem Assessment

2005). Despite being a global concern to sustain and protect biodiversity, biodiversity loss is increasing (Isbell 2010). The major causes of biodiversity loss include habitat fragmentation and destruction, overexploitation of selected species, hunting, introduction of exotic/invasive species, pollution, control of pests and predators and climate change (Barnosky et al. 2012).

Given the importance of biodiversity, conservation strategies are currently focused on maintaining and increasing it around the world (Wanjui 2013). Mayer (1988) introduced the term “hotspot” for the ten tropical forest areas with extraordinary number of endemic plant species and a high level of habitat loss. Identifying these hotspots highlight biodiversity rich areas under the acute threat and can focus research priorities for conservation (Myers 1988). A habitat is considered a hotspot if it meets two strict quantitative criteria. First, the region has to contain at least 1,500 vascular plants as endemics (>0.5% of the world's total) and second, it has to have 30% or less of its original vegetation (extent of historical habitat cover) remaining. A total of 35 regions across the globe now meet the hotspot criteria with each region holding at least 1,500 endemic plant species and each having lost 70% or more of its original habitat extent. These regions collectively hold not less than 50% of vascular plants and 42% of terrestrial vertebrates (amphibians, mammals, birds and reptiles) as endemics (Mittermeier et al. 2004). Combined, the 35 hotspots (listed in Table 1) once covered a land area of 23.7 million km<sup>2</sup>, or 15.9% of Earth's land surface, approximately the size of Russia and Australia together. However, as a result of habitat destruction in these areas over the past century, what remains of the natural vegetation in these areas is now just 2.3% of the world's land area (~3.4 million km<sup>2</sup>), slightly more than the land area of India.

In contrast with the terrestrial biome, data on the distribution and status of aquatic species are just beginning to be synthesized at a global scale. Roberts et al. (2002) have provided the first comprehensive global assessment of conservation priorities for coral reefs, an aquatic ecosystem, and brought much-needed attention to

marine hotspots. Coral reefs represent the highest point of marine diversity (Reaka-Kudla 1997) but are seriously threatened by human activities such as ocean warming and acidification (Hoegh-Guldberg et al. 2007). Data on marine habitats remain scarce compared to information on terrestrial ecosystems (Sala and Knowlton 2006), and the lack of knowledge about freshwater systems is even more pronounced. However, significant advancements are being made on aquatic biodiversity such as the Global Freshwater Biodiversity Assessment (Darwall et al. 2005) and the Global Marine Species Assessment, which includes comprehensive status assessments completed for reef-

forming corals (Carpenter et al. 2008). Although not entirely free from criticism (Marchese 2015), the hotspot approach has played an important role in conservation prioritization. Since it is not possible to conserve all biodiversity due to lack of resources, international conservation agencies have used it as the most effective approach to minimize species extinctions on a global scale. However, focusing all the conservation attention on biodiversity hotspots could create a disproportionate impact on the maintenance of biodiversity in other biomes. For instance, although desert ecosystems cover 17% of the world’s landmass and harbor surprisingly high biodiversity, they have not received substantial financial support for conservation actions (Durant et al. 2014). More integrative strategies, which enable the conservation of biodiversity from all habitats, can better identify areas of high conservation priority.

Conclusions

The impacts of biodiversity hotspots on conservation have been diverse and profound. For instance, several project prioritizing conservation strategies were well supported by the funding agencies across the globe after the introduction of the hotspot concept. Identifying hotspot regions will help provide primary data on marine, fungal, invertebrate, and microbial diversity to ensure the conservation of biodiversity in holistic way.

## Huddling

Carsten Schradin<sup>1,2</sup> and André Ancel<sup>1</sup>

<sup>1</sup>Université de Strasbourg, CNRS, IPHC UMR 7178, Strasbourg, France

<sup>2</sup>School of Animal, Plant and Environmental Sciences, University of the Witwatersrand, Johannesburg, South Africa

## Synonyms

Aggregation; Clustering; Clumping; Crèching; Grouping; Group nesting; Nest sharing

## Definition

Huddling is defined as mutualistic social thermoregulation where two or more animals are in body contact, increasing body temperature (ectotherms), or decreasing costs of thermoregulation (endotherms). Typically, huddling occurs in resting (including sleeping) individuals, but

in penguins it can also occur in moving individuals (moving huddles of breeding emperor penguins and crèches of juvenile emperor and king penguins; *Aptenodytes forsteri* and *A. patagonicus*).

## Introduction

Individuals can save costs of thermoregulation by using torpor and hibernation and/or by huddling, i.e., two or more individuals are in body contact and share in the metabolic thermogenesis of each other (Gilbert et al. 2010). As all individuals benefit at the same time when huddling, this represents a form of mutualistic cooperation. Huddling permits individuals to minimize heat loss and thereby lower their energy expenditure (Ancel et al. 1997) and possibly allows them to reallocate the saved energy to other functions such as growth or reproduction (Gilbert et al. 2007a). Huddling is especially important when animals face high heat loss, such as small animals with a high surface-to-volume ratio, individuals living in cold environments, or individuals experiencing poor insulation during molt. Huddling conserves energy and allows individuals to reduce their metabolic rate, lower their food intake, decrease their body mass loss, reduce their water use, increase their growth rate, and maintain a more constant body temperature. Thus, huddling is adaptive, probably increasing survival probability and reproductive success.

## Where Does Huddling Occur?

Huddling occurs in both invertebrates and vertebrates. Examples for huddling insects are monarch butterflies (*Danaus plexippus*) forming large aggregations in their overwintering trees in Mexico (Brower et al. 2008). Here, thousands of butterflies huddle closely together, covering entire trees. Honey bees (*Apis mellifera*) are another example: here the entire colony huddles together at night and from autumn to spring, when it is too cold for them to go out and forage. Clusters of hundreds to thousands of overwintering spiders in

close body contact have also been observed, and the same phenomenon is known from ladybirds.

Huddling also occurs in ectotherm vertebrates. Many amphibians and reptiles including lizards and snakes share overwintering refuges, where they rest close to each other in body contact.

Among birds, huddling has been observed in at least 23 species (including partridges, quails, swallows, pelicans, cormorants, and penguins) (Gilbert et al. 2010). Juvenile emperor and king penguins and breeding emperor penguins form huddles from hundreds to thousands of individuals. In contrast to most other species, individuals in these huddles are not resting but moving, creating metabolic heat, moving the egg on their feet (emperor penguins) such that they get evenly warmed, and potentially competing for the warmest spots in the huddle. Huddling is also common in mousebirds (family Coliidae, living in southern Africa), which form groups of up to 20 individuals. Mousebirds huddle closely together when resting at night or during cold winter days (frost being possible in South Africa).

Huddling is very common in small mammals such as bats, shrews, and rodents (Canals et al. 1989). Many bat colonies are characterized by individuals huddling together. Many species of rodents huddle together during their resting period. Many species of shrews and rodents that are solitary during the breeding season become sociable afterward and then form huddling groups. Other small mammals such as social mongooses, for example, meerkats (*Suricata suricatta*), also huddle closely together in their den during their resting period. But huddling also occurs in large and very large mammals, such as resting wild boar (*Sus scrofa*), and southern elephant seals (*Mirounga leonina*) during their 1-month lasting molt when they renew their hair and their cornified epidermis, making them vulnerable to loss of body heat (Chaise et al. 2018). Last but not least, huddling is also very common in humans, for example, pairs sharing their bed, a huddle which will very quickly attract their children too. In humans, huddling is even recommended officially as a safety measure in emergency situations, such as evacuating a boat in lifeboats, or during alpine disasters.

## Benefits of Huddling

The function of huddling is to improve thermoregulation. Monarch butterflies create a beneficial microclimate by huddling closely together in trees (Brower et al. 2008). Inside the huddle, it is significantly warmer during the night and significantly cooler during the day, with higher relative humidity throughout the day. Thus, butterflies in the huddle get some protection from freezing, might reduce their rate of lipid burning, and lower their rate of water loss (Brower et al. 2008). In colonies of bees, the effects on the microclimate are even stronger, as they do actively increase the temperature by shivering, keeping the temperature between 27 °C and 34 °C. The workers rotate through the huddle from the outside (approx. 9 °C) into the warmer center.

In birds and mammals, huddling is regarded as a form of social thermoregulation to minimize heat loss and thereby lower energy expenditure (Gilbert et al. 2010; Scantlebury et al. 2006). Through huddling, birds can reduce their energy expenditure by 6 to 50% and mammals by 8 to 53%, depending on the efficiency of huddling (Gilbert et al. 2010), varying according to group size, ambient temperature, intensity of huddling, and species (Fig. 1).

Emperor penguins are well insulated, but huddling is the key energy-saving mechanism for males to endure their 4 months incubation fast during the Antarctic winter, when their energy expenditure is decreased by 16% (Ancel et al. 1997). The birds huddle at nighttime, and the maximum ambient temperature recorded inside a huddle was 37.5 °C (ambient temperature was −19 °C), which is close to the birds' deep body temperature (Gilbert et al. 2006). Without the possibility to huddle, reproductive success decreases significantly, as the period males can fast (incubate the egg without feeding) decreases and as such the percentage of males that desert their egg increases (Gilbert et al. 2007a).

Huddling permits newborn altricial mammals such as mice and rabbits to decrease their metabolic rate, to increase their growth rate, and to acquire faster their thermoregulatory capacities

(Gilbert et al. 2007b). In African striped mice (*Rhabdomys pumilio*), solitary sleeping individuals spend up to 50% more energy than individuals sleeping in huddling groups, and reduced costs of thermoregulation by huddling are believed to be the main reason for group-living in this species (Scantlebury et al. 2006). Theoretical models and empirical studies indicate that the optimal size for huddling groups is 4–6 individuals. Energetic benefits due to huddling are more prone in small animals, which are facing a higher heat loss due to a higher surface-to-volume ratio than in large animals. This can explain why huddling is more common in small than in large mammals. However, huddling can also occur in large species. Female southern elephant seals huddle in mud pools, allowing them to molt faster and with this to reduce the time spent fasting on land (Chaise et al. 2018). Huddling in sleeping groups at night might even have been an important adaptation allowing a naked species of apes, humans, to colonize areas outside of the tropics.

Small body size, poor insulation, and living in cold environments are factors increasing the benefits of huddling, thus favoring its evolution. Increased benefits in cold environments can also explain why many species of small mammals form huddling groups especially in winter. In sum, huddling allows ectotherms to increase body temperature and endotherms to reduce energetic costs of thermoregulation, possibly allowing them to reallocate the saved energy to other functions such as growth, survival, and reproduction.

## Costs of Huddling

Being in close proximity with conspecifics can be very costly in terms of the risk of getting infected by ecto- and endoparasites as well as by other pathogens. Bird nests, where chicks are huddling together, are often heavily infected by mites and fleas. Huddling rodents such as striped mice regularly change nesting sites, possibly to avoid the spread of ectoparasites. However, studies testing in how far huddling leads to an increased risk of getting infected by parasites and other pathogens are mainly missing.

**Huddling,**

**Fig. 1** Examples of endotherm species saving energy by huddling. Top: Huddle of thousands male emperor penguins during the incubation period at Dumont d'Urville. Inside the huddle, the temperature can reach  $37^{\circ}\text{C}$  despite the ambient temperature is  $-19^{\circ}\text{C}$ , reducing costs of thermoregulation, leading to a decrease of energy expenditure by 16%. (credit: CNRS/IPEV/DEPE). Bottom, infrared-recording from striped mice huddling together at night in a natural nest. Even in summer, night temperatures in the habitat of that species, the Succulent Karoo semidesert of South Africa, can go down to  $5^{\circ}\text{C}$ . Striped mice sleeping alone spend up to 50% more energy at night than striped mice sleeping in huddling groups. (credit: C. Schradin)

H

**Proximate Mechanisms of Huddling**

Individuals often aggressively defend territories and resources and keep a distance from each other, especially during the breeding season. However, to come into very close proximity to huddle, individuals must be nonaggressive toward each other and be attracted by each other. In many species that are solitary and aggressive during the breeding season, such as shrews and some species of voles, the behavior changes in the non-breeding

season: they become less aggressive and instead show amicable behavior toward conspecifics to which they are attracted. Thus, the cessations of aggression and instalment of amicable behavior together with being attracted either by each other or to the same resting place are essential mechanisms allowing huddling. Endocrine mechanisms associated with this include a decrease of reproductive hormones after the breeding season, especially of testosterone and progesterone. In species that are gregarious and form huddling groups also

during the breeding season (these groups typically consist of close kin such as family groups), neuronal networks in the brain allow for such a form of social organization. One mechanism that has been discussed here is the expression of the estrogen receptor  $\alpha$  in male rodents.

## Conclusion

Animals huddle together either to increase their body temperature above ambient (ectotherms) or to reduce the energetic costs of thermoregulation (endotherms). Huddling thus evolved when the benefits of improved thermoregulation were higher than the costs of reduced aggression (to enable proximity) and increased risk of infection. This depends on the body size, life history, and ecology of the species, explaining why huddling is more common in small species and during the cold non-breeding season.

## Synonyms

[Approach test](#); [Avoidance test](#); [Voluntary animal approach](#); [Voluntary approach test](#)

Animal's perception and response to humans are associated with the animal's species, experience with humans, nature of the interaction, motivational state, temperament, age, genetics, and can even be influenced by rearing environment conditions and prenatal stress levels (Claxton 2011; Sherwen and Hemsworth 2019; Slaney et al. 2018; Waiblinger et al. 2006). These key

components are determinants in establishing a human–animal relationship, which can be classified in three ways: negative, where the animal exhibits fear to humans and avoids its proximity or contact; neutral, where the animal manifest low levels of fear, but still avoids human contact; and positive, when there are no fear manifestations and the animal is confident with people (Claxton 2011).

In this context, the Human Approach Test is a task used to assess human–animal relationships and to monitor animal welfare. In laboratory animals, this test is also used to evaluate motivated behavior or anticipation towards rewards (Arhant and Troxler 2017; Augustsson et al. 2002; Dalla Costa et al. 2016; Ishiyama et al. 2019). Briefly, by recording the animal's reaction to a standing or approaching human, this test evaluates the latency, distance, and behavior of the animal towards a human. This test has variations depending on the experimental procedure and measures of interest, where we find: Voluntary Animal Approach: in which the animal approaches a stationary human, and Avoidance/Approaching Test: where the human approaches the animal, and the distance and manner in which the animal reacts is determined. Also, depending on the experimental procedure, this test can measure the impact of human–animal interaction on the animal's emotional state, its affiliative, aggressive, ambivalence, or fearful behavior towards humans, and correlate them with physiological or productive parameters. This test has also been complemented with reports, questionnaires, or evaluation of the stock person, zoo-keeper, shelter staff, or owner's opinion or behaviors towards the animal. The measurements selected for evaluation in this test should ideally be determined considering their validity (i.e., measure's scientific validation, specificity, and accuracy) and reliability (i.e., precision, sensitivity, consistency, and resolution). Also, this test usually requires observers or experimenters training, as well the assessment of interobservers evaluation, determining the degree of correlations and consistency of their reports (Arhant and Troxler 2017; Bergamasco et al. 2010; Breuer et al. 2000; Carlstead 2009; De Meester et al. 2011; Gourkow

et al. 2014). Due to the nature of the human–animal relationship and the context of their interaction, this test presents some variations when being assessed in domestic, zoo, and laboratory animals.

## Use in Domestic Animals

This test is used in pets and farmed animals (including pigs, poultry, horses, small and large ruminants, and fur animals, such as foxes and mink) to evaluate the human–animal relationship and as an indicator of animal welfare. In pets, the Human Approach Test has an important part of behavioral testing and evaluation of a pet's temperament, allowing the identification of behavioral problems. This is also relevant in rescue shelter animals and useful for predicting the animal's best “pet-owner match.” Also in these animals, Human Approach Test is used to evaluate and monitor the animal's emotional state before and after changes in human animal-interaction, examining their affiliative, aggressive, anxious, content, or frustrated behaviors (De Meester et al. 2011; Gourkow et al. 2014; Hewison et al. 2014; Martínez-Byer et al. 2020; Waiblinger et al. 2006; van der Borg et al. 1991). Emotional reactivity has also been evaluated in a productive context and used to assess animal welfare, wherein pigs and silver fox, Human Approach Test has been correlated to the animal's vocalization responses or heart rate as a measurement of emotional state (Gogoleva et al. 2010; Leliveld et al. 2017). Due to the tight relationship of pets with humans, the Human Approach Test is frequently implemented using familiar or unfamiliar humans in different behavioral contexts, for example, standing, walking, talking, looking directly at the eyes of the animal, or attempting to touch. This capacity to recognize and increase an approach towards a familiar person is not restricted to pets, but it is also present in farm animals like calves (Hewison et al. 2014; Kerepesi et al. 2015; Rousing et al. 2005; van der Borg et al. 1991).

Particularly in domestic animals, the tight-contact between these animals and humans

makes human posture relevant, so this test can be accompanied by aggressive or submissive signals from the human. This approach has been used in rescue shelter dogs, where in order to assess and monitor animal welfare and to evaluate the impact of a human–animal interaction program, authors used the Human Approach Test including the use of a friendly or threatening human, in addition to other behavioral tasks, while they also evaluated the dog’s heart rate and salivary cortisol as physiological parameters (Bergamasco et al. 2010). Other variations of this test include the use of neutral, threatening, or friendly approaches from humans associated to different stimuli (e.g., an artificial hand, flapping blanket, sound stimuli, doll, and dogs), with or without the presence of the owner, in order to assess a dog’s temperament and social behavior (De Meester et al. 2011). This has also been evaluated in horses, establishing that these animals prefer to approach to an unfamiliar human with a submissive posture (i.e., closed body posture: slouching, hands in front of the body, feet close to each other, relaxed knees, and hunched shoulders) over one with a dominant one (i.e., open body posture: standing tall, puffed chest, hands placed on the side, shoulders squared, and feet hip-width apart) (Smith et al. 2018). In respect to the uses of the Human Approach Test in farm animals, these measures are mostly assessed: Avoidance Test, referred to as the minimal distance that the animal tolerates for a human to approach; Voluntary Animal Approach, which measures the voluntary approach behavior of an animal towards a stationary human; and the measurement of the animal’s reaction to handling. Considering the agriculture and productive context of farm animals, the effect of human–animal interaction is relevant to evaluate in these animals, due fear of humans can be a detrimental factor that impacts its well-being, animal profitability, productivity, and affects the quality of the final product. This has been observed in cows, where it was determined that less approach to a stationary human was correlated with low milk production. Also in hens, where fear of humans was correlated with low egg production. Fear of humans also has metabolic costs, affects reproductive success, induces acute and chronic stress, and an animal’s

escape attempts from humans can predispose them to injuries and even death (Barnett et al. 1992; Breuer et al. 2000; Dalla Costa et al. 2016; Rousing et al. 2005; Waiblinger et al. 2006). These findings make assessing human–animal relationships not only a welfare issue but also an economical one.

## Use in Zoo Animals

Approach Test has been implemented using zookeepers, visitors, conspecifics, novel objects, and obstacles; however, due to bioethical conflicts and potential safety hazard for humans and animals, direct Human Approach Test is more difficult to assess in this context (Carlstead 2009; Hardie and Buchanan-Smith 2000). To overcome this problem, Carlstead (2009) used a test called “Keeper Calling Animal,” in which both the animal’s looking, approaching, ambivalence, or aggressive reactions to its zookeeper’s call (outside of the enclosure), as well as the zookeeper behavior, evaluating verbal, locomotor, gestures, non-verbal noise intensity, and body posture are recorded. Another variation of this test includes the determination of an animal’s “visitor effect,” observing the animal’s approach or avoiding behavior towards visitors (Sherwen and Hemsworth 2019). Since it has been established that developing a good human–animal relationship is also a potential tool of environmental enrichment, which must maintain the goal to ensure a positive experience for both human and captive animals, while it also satisfies the zoo’s mission (Claxton 2011), it is relevant to develop experimental procedures to evaluate the welfare impact of this relationship and develop a Human Approach Test both safe for both humans and animals.

## Use in Laboratory Animals

In laboratory animals, the Human Approach Test has been used in social animals, like rats, to assess the animal’s motivation for human contact (Augustsson et al. 2002). In these species, the

use of heterospecific play allows to not only measure the rewarding value of “tickling” and of “rough-and-tumble play,” but it also allows the assessment of a Human Approach Test using the experimenter’s hand, which is used to determine the latency and velocity to approach the hand to be tickled, or to identify signs of anxiety and fear (Burgdorf and Panksepp 2001; LaFollette et al. 2018b). This test can be performed in the home cage or a “test cage,” where it can also evaluate the time near an experimenter’s stationary hand, the interaction and direct contact to the hand, the location of the rat in the cage, and burrowing behavior. Also, the Human Approach Test has the advantage that it can be determined in one or multiple rats at the same time (Cloutier et al. 2018; LaFollette et al. 2017).

Using the “tickle” task, the Human Approach Test can be evaluated before, immediately, or even days after tickling, observing a decrease in the latency to approach the hand immediately after tickling and having mixed results when it is determined days later (LaFollette et al. 2017). In rats, it was determined that social isolation decreased the latency in the Human Approach Test (Burgdorf and Panksepp 2001). Also as an indicator of motivation, it was observed that a slowly approaching human hand, in anticipation of the act of tickling, evoked hedonic vocalizations at a frequency of 50 kHz (Ishiyama et al. 2019). The Human Approach Test has also been used in a Pavlovian conditioning study (Cloutier and Newberry 2008), in which the act of tickling was paired with an intraperitoneal injection of saline solution, in order to determine the rewarding aspect of tickling and the reduction of stress in routinary laboratory procedures. In this experiment, after conditioning and using a Y-maze, the rat was allowed to choose between the hand of an unfamiliar experimenter placed in one arm of the maze or a mock-hand located on the other. The latency, the number of visits, entries, and time spent in each arm were evaluated. Since laboratory animal welfare is not only a bioethical issue but fear and anxiety in routinary procedures can also interfere with experimental conclusions, it is relevant to evaluate human–animal relationships in a

laboratory context. These tests can even be determined in less social animals, like mice, observing a decrease in the latency of approaching after non-aversive handling. This determination is also important in pet stores, where due to an increase conception of rodents as pets, the relevance of assessing human–animal interaction using the Human Approach Test, particularly using unfamiliar humans, acquires more relevance due to the animal’s welfare (Augustsson et al. 2002; Hurst and West 2010; LaFollette et al. 2018a).

## Conclusions

In the evaluation of the human–animal relationship, it is also relevant to determine animal welfare, where Human Approach Tests are part of the behavioral battery test used to assess their impact. Depending on the animal species and measures of interest, different experimental procedures can be applied, such as approach or avoidance to a standing or moving human (associated or not to different visual stimuli), or determination of an animal’s reaction to handling, allowing to assess: animal welfare, fear to humans, identify behavioral problems, evaluate an animal’s temperament or personality, social motivation, or monitor the impacts of human–animal interaction. These determinations can also be correlated with physiological or productive indicators of the animal, and ideally, the selected measurements evaluated should be determined by their reliability and validity. Also, this test is usually complemented by the assessment of the behavior or opinion of the human about the animal, as well by the degree of confidence and correlation of interobservers records. These tests are frequently used in domestic and laboratory animals, and less frequently in zoo animals, due to bioethical issues and human–animal safety hazard. The Human Approach Test is a useful tool for determining the impact of the human–animal relationship in a domestic, productive, and scientific context, having, in this matter, a social (in the case of pets), economic (farmed animals), and scientific (zoo and laboratory animals) relevance.

## Definition

Cooperation refers fundamentally to the exchange of ideas, material goods, or labor in pursuit of common interests held by two or more individuals. Whereas classical perspectives consider cooperation to be the opposite of competition, current evolutionary approaches hold that cooperative behaviors are often essential during competitive exchanges, especially as the size of competing groups increases.

## Introduction

The study of cooperation in human societies holds substantial import for several disciplines, ranging from economics and political science to mathematical biology and evolutionary psychology. This entry focuses on four key theoretical developments in approaching cooperation in human evolutionary biology and psychology. In particular, this entry covers the early formative theories of reciprocal altruism and kin selection as well as more recent developments in cultural group selection and multilevel selection theory.

## Reciprocal Altruism

Early evolutionary theories of cooperation sometimes found explanations of cooperative behaviors to be challenging to reconcile theoretically. One key difficulty for such theories was the advantages derived by so-called free riders of a social group (Dawkins 2006). In free-riding situations, individuals take advantage of a social group by exploiting their collected resources and labor without personally incurring any costs. The greater individual success of free riders over cooperators caused some theorists to assume that selection for cooperation should be lessened in groups with increased numbers of free riders in the population. Reciprocal altruism provided one of the first definitive solutions to these problems by demonstrating the situations when and reasons why individuals would concede some personal benefit to help an individual who is unrelated to them. Today, the explanatory breadth of reciprocal altruism appears limited in comparison to when it was first introduced; however, it still holds foundational importance to theories on the evolution of altruistic cooperative behaviors.

Trivers (1971) specified three initial preconditions for reciprocal altruism to continuously arise in social interactions among group members: personal recognition, frequent interaction, and memory of past actions. In the first case, individuals must be able to recognize those they interact with in order to differentiate individuals who have helped themselves or others in the past from those who have not and therefore may be acting as free riders. Secondly, if these individuals do not interact frequently, they will be less likely to build a mutual rapport to provide incentives for further cooperation. Lastly, individuals who do not remember the relative benefits received and costs incurred during prior cooperative acts cannot be expected to effectively reciprocate, given the time delay that is often present in reciprocal interactions.

As identified by Patton (2000), altruistic behaviors such as sharing, mutualistic labor, and coalitional combat appear to be evolutionarily linked to reciprocity. Further, reciprocal behavior reduces the individual and collective risk of

pursuing certain aims, such as multi-day hunts or violent combat. This does not, however, eliminate certain risks, such as accidental cooperation with free riders. Nowak and Sigmund (2003) discuss responses to similar risks in describing indirect reciprocity, where the reputation of an individual correlates with the relative payoff they are expected to receive in a cooperative arrangement. Individuals who choose to free-ride are more likely to develop a negative reputation and be socially excluded from cooperative endeavors, thus limiting the benefits they are capable of accumulating and incentivizing cooperation.

## Kin Selection

The theory of kin selection is originally traceable to J.B.S. Haldane. It describes the differential pathways by which individuals can achieve reproductive success without, or in addition to, personal reproduction. In models of kin selection, this concept is primarily understood through an understanding of the distribution of an individual's genes throughout their close and distant kin. Closer relatives possess greater genetic similarity with each other, thus hypothetically impacting their behavior when interacting. More distant relatives are less likely to cooperate as consistently and closely as near relatives but are still more related than non-kin and thus may behave differently in certain contexts.

Kin selection is represented in various forms throughout the literature. In Maynard Smith's conception (Smith 1964), a trait is increasingly likely to be favored as the degree of genetic relatedness between two individuals increases. In Hamilton's conception (Hamilton 1970), a trait's indirect-fitness consequences are the most influential in determining whether or not it is selected for. Lastly, in Frank's (1998) view, kin selection distinguishes between direct and indirect selection in all natural selective processes. As a result of these variations, kin selection has often been used to describe substantially different phenomena and scientific theory; however, the core ideas of Hamilton appear to underpin most conceptions both historically and today.

Kin selection was first formalized mathematically by Hamilton (1970) in his work on the likelihood of altruism between close and distant kin. Hamilton formulaically depicted this with a simple inequality:

$$rB > C$$

Here,  $r$  provides the coefficient of relatedness between two individuals,  $B$  represents the benefits derived by an act of altruism, and  $C$  represents the costs incurred by an act of altruism. Though formative in the early days of kin selection theory and still influential today, the wide use of this formulation, known as Hamilton's rule, has been critiqued by Nowak et al. (2017), who claim that its derivation is not actually testable empirically.

Madsen and colleagues (2010) attempted to test kin-selected behavior according to Hamilton's rule with two experimental models in South Africa and the United Kingdom. The authors found that individuals were more likely to act altruistically and willingly incur a cost as relatedness to the person benefitting from their action increased. However, they noted that reciprocity and age of the recipient of the altruistic act maybe confounds of the study. Kin selection has also been studied in various field studies, but many of these attempts have been critiqued for not including the often temporally distant costs and benefits, relative to population structure, of altruistic actions (Nowak et al. 2017). As a result, beyond some experimental and observational paradigms in humans, the most persuasive evidence for kin selection is still derived from nonhuman literature.

## Multilevel Selection and Cultural Group Selection

Beyond reciprocal altruism and kin selection, in the 1960s, it was proposed that between-group competition could also lead to the evolution of within-group cooperation (i.e., *group selection theory*). Although group selection theory was initially well received, several researchers criticized the perspective on the basis that genes, rather than

individuals or groups, featured the necessary characteristics for replication (Dawkins 2006). Critics also argued that groups' homogenization due to individual dispersal reduces the likelihood of natural selection operating at the group level (Dawkins 2006). Moreover, mathematical models identified that in the absence of kin selection and reciprocity, groups of altruists were susceptible to the invasion of free riders leading to the extinction of this prosocial strategy (Dawkins 2006).

Even though some evolutionary biologists continue to insist that group selection is not supported on both theoretical and empirical grounds, several researchers have reexamined the ongoing debate and reached an epistemological compromise. For instance, Damuth and Heisler (1988) identified that most of the criticisms directed toward group selection stemmed partly from the obfuscation of two types of multi-level selection: MLS1 and MLS2. Per the authors, in MLS1, group selection concerns the effects of group membership upon individuals' fitness, wherein both phenotypes and fitness are individual-level properties. Consequently, a hierarchical structure emerges with individuals nested within groups and groups contained within populations. Evolutionary inferences are limited to changes in the frequency of individual phenotypes within a population. Conversely, in MLS2, group selection describes a change in the frequency of different types of groups, with groups varying in their phenotypes and fitness. Evolutionary extrapolations are restricted to the estimated change in the frequencies of groups within a population. Okasha (2009) further distinguished MLS1 and MLS2 according to how the unit of selection, either individuals or groups, reproduces. Whereas under MLS1 only individuals reproduce, in MLS2, groups have the ability to sire other groups. Hence, most of the criticisms directed toward MLS, in general, are limited to MLS2 dynamics.

In recent years, several researchers have adopted an MLS (mostly concordant MLS1) perspective for understanding human cooperation in an array of social contexts, including lethal coalitional aggression. For instance, Walker and Bailey (2013) interpreted the number of war

casualties in lowland Amazonian societies through an MLS lens. Per the authors, these societies' levels of intense and frequent conflict could be attributable in part to the high between-group genetic variance observed. According to their review, isolation, small population sizes, and genetic drift allowed Amazonian communities to attain high autosomal  $F_{ST}$  scores, an indicator of genetic differentiation, compared to other human societies around the globe (~15%). Similarly, current estimations suggest that relative to other sociopolitical systems, Amazonian communities exhibit lower intragroup genetic heterozygosity, increasing their likelihood of within-group cooperation. Although several authors have argued that warriors attain a direct fitness benefit from raiding rival communities (e.g., the Yanomamo in Venezuela), recent studies have found that this pattern does not generalize well to other small-scale societies characterized for their high frequency and intensity of between-group conflict (e.g., in the Waorani, belligerent individuals have fewer offspring; Walker and Bailey 2013). Moreover, for the authors, mechanisms of cooperation, such as direct reciprocity and mutualism, do not provide a satisfactory explanation for the evolution of blood feuds and revenge cycles among these societies, wherein individuals do not necessarily attain any direct benefit. Consequently, MLS could explain the persistence of lethal coalitional formation even in situations where individuals do not obtain a direct fitness benefit.

Even though kin selection and reciprocal altruism are often considered to be adequate evolutionary forces involved in the emergence of cooperation within small-scale societies, in larger communities, anonymity and one-time interactions increase the risk of defection and the collapse of large-scale cooperation. In response to these theoretical limitations, Richerson and Boyd (2008) proposed that sizable societies could maintain considerable levels of cooperation by evolving punitive institutions to limit the spread of free-riding behavior. Likewise, Bowles and Gintis (2013) suggested that intragroup cooperation in large groups emerges in part due to the effects of strong reciprocity. According to this framework, individuals are willing to punish

defectors, even if this behavior entails a cost to the punisher and benefits the group. Bowles and Gintis also argued that within-group cooperation and intense between-group competition covary across human societies. The authors' mathematical models and empirical evidence indicated that societies featuring high in-group prosocial biases and out-group antagonism (i.e., parochial altruism) outcompeted rival groups displaying higher levels of within-group competition.

Although critics have claimed that genetic differentiation among human groups is not sufficient to sustain within-group cooperation, Richerson et al. (2016) proposed that cultural differentiation (i.e., as reflected by cultural  $F_{ST}$  scores) could provide enough behavioral intergroup variation for selection to operate. The authors collected information on individuals' beliefs and behaviors from various online surveys (e.g., World Values Survey, Scottish Health Survey, and Afrobarometer, among others) and estimated cultural  $F_{ST}$  values for numerous human groups. Above and beyond differences in group size, the authors determined that most cultural  $F_{ST}$  scores were greater than 0.01, with several traits surpassing a 0.05 threshold and consequently generating the necessary conditions for cultural group selection to take place. The analyses also revealed that cultural  $F_{ST}$  was considerably larger than genetic  $F_{ST}$ , indicating a greater probability of group selection acting directly upon cultural variation, rather than on genetic differences between groups. It is worth noting, however, that these examinations did not discriminate between MLS1 and MLS2.

## Discussion

This entry provides a description of some of the key theoretical approaches to the study of cooperation in humans. The bases of contemporary work on the topic are described using reciprocal altruism and kin selection theory. Problems with both of these early evolutionary theories have led contemporary researchers to different solutions that either supplant or subsume those early approaches within other frameworks. A couple

of those approaches seen commonly today are the theories of cultural group selection and multilevel selection, both depicted here.

| <i>Triadic engagement:</i> | infants coordinate attention between a social partner and an object of mutual interest.                                                                     |
| <i>Joint attention:</i>    | a form of social cognition; a cluster of behavior that shares the common goal of communicating with another person about a third entity in a nonverbal way. |
| <i>Prosody:</i>            | the rhythm of language and the way a speaker's voice rises and falls.                                                                                       |
| <i>Imitation:</i>          | the reproduction or performance of an act that is stimulated by the perception of a similar act by another person.                                          |
| <i>Social Referencing:</i> | the process wherein infants use the affective displays of an adult to regulate their behaviors toward the environment.                                      |

**Extended period of dependency.** Humans are unique in that they are born highly dependent on others for survival, and this dependency lasts several years, often the first decade of a child's life. This is often referred to as the extended period of dependency. There are various theories regarding the function or purpose of this extended time. There is, however, a general consensus that this period of time serves a particular function or purpose in the human species. It has been speculated that this extended period of dependency allows for the infant to begin the process of social learning and forming an attachment with a caregiver (Bowlby 2005; Gergely 2006). It may, in fact, allow for human cultural learning – a kind of social learning or transmission of information through a social process that, while it exists, is unmatched in other species. During this extended period, human infants not only have time to bond exclusively to those who are caring for them, but also there is time to learn information from those caregivers. It is thought that this extended time for learning from others is the key element that allows humans to develop and transmit information that enables complex cultures to form, transmit, and maintain information.

One theory regarding the specificity of human cultural learning is that humans are born premature and thus dependent on others for survival for an extended period of time. During this time, human caregivers have the opportunity to bond emotionally with the infant and begin the process of this teaching-learning system that will eventually allow them to learn the relevant information to ensure survival. The infant and caregiver develop their nonverbal communication system, which allows them to bond and share information. This emotional bond allows for infants to develop within a teaching-learning or pedagogical system with the primary caregiver.

Cultural learning is critical to human survival (Boyd et al. 2011). Consider that humans (one single species) have spread all over the globe, surviving in extremely diverse ecological contexts. It is argued that cultural learning enables such survival (Boyd et al. 2011). If one were to suddenly arrive in the arctic or the savannah without other humans to learn the key elements of survival, it would be impossible. The ability for humans to transmit culturally relevant information to one another is thought to allow human learning and therefore survival in different contexts. Each cultural context allows infants to be born into an opportunity for learning, as the learning system transcends diverse cultural contexts. Human infant minds are adaptive and flexible (also seen in patterns of brain development) allowing them to mold to the particular cultural context and focus and learn the relevant information needed within that context.

**Attachment facilitates learning.** Infants are born highly dependent on the protection and provisioning of primary caregivers for survival (Ainsworth 1979; Bowlby 2005). But that is not all. Nearly a century of research tells us that infants need affection and bonding to survive and thrive (Ainsworth 1979; Bowlby 2005). Without such love and care, human infants and young children do not develop in ways that are typical for most children, with deficits in cognitive abilities, intelligence, and even language development (Chisholm et al. 1995). However, with care, infants and caregivers form an intense bond. The infant learns that the caregiver is their secure

base – someone from whom they can depend upon (Bowlby 2005). It is thought that this attachment is the foundation for all other relationships later in life. From this early emotional bond, infants learn that other relationships are dependable – a safe and secure base from which they can explore the world (Bowlby 2005; Waters et al. 2002). The idea is that they develop and later form a mental model based on this first relationship (Stern 2018). At the core of Attachment Theory is the idea that the infant must develop an emotional bond to one primary caregiver, and this primary caregiver is typically the mother (Broesch et al. 2021). However, there is also evidence in the field of anthropology – typically extrapolated from qualitative ethnographic methodology, but also some quantitative observations of infants and young children across diverse societies, indicating that infants may be cared for by multiple caregivers (Tronick et al. 1987; Keller 2013). This evidence suggests that infants may be capable of attaching to multiple caregivers with no primacy of the mother.

**Sensitive parenting enables attachment.** Achieving a secure attachment requires sensitive caregiving. Attachment research has found that caregivers who respond in a sensitive, timely, and appropriate manner to their infants have children who demonstrate a secure attachment to their caregiver in the first few years of life. Sensitive responding is a vague and fuzzy concept that, until recently, was investigated primarily with mother-infant dyads in Western societies (Broesch et al. 2016; Keller 2013). We now know that responding to infants in a consistent manner appears to shape their developing social expectations and aid in forming a secure relationship with the caregiver. In fact, infants show a preference for other adults with the same responsive signature as their primary caregiver (Bigelow and Rochat 2006). This suggests that they are forming expectations and preferences for social behaviors even in the first few months of life, which is quite remarkable. Research examining parental responsiveness indicates that infants as young as a few months of age are sensitive to the timing of the caregiver's response – typically responding within 1 s of the onset of an infant's behavior.

Accordingly, infants also show distress to a break in the social interaction – referred to experimentally as the “still face” paradigm (Rochat 2001). Around 5 months of age, when there is a sudden break in a dyadic social interaction between an infant and another individual, the infant responds with distress and negative emotional expressions. This research suggests that infants are not only forming an emotional bond, but they are developing expectations regarding the pattern of interaction. Sensitive parenting is correlated with secure attachment, but what are the critical elements of sensitive parenting?

**Mutual joy as a critical aspect of sensitivity.**

Although infants are communicative and responsive from the outset, it is not until sometime between the 5th and 8th week of life that they begin to produce a social smile. A social smile is a smile in response to social interaction – typically gazing into the others' eyes and responding to an interaction – verbal or facial (Wörmann et al. 2012; Messinger and Fogel 2007). At this point, we see infants show the first signs of delight at enjoying the social company of another. They gaze into the eyes of a smiling caregiver and smile in response. These moments of “mutual joy” (Broesch and Carpendale 2021) set the stage for early communication. What is often overlooked is the emotional element to early communication; yet, it is present and clear from very early in life. While research suggests that the caregiver plays a vital role in helping infants and children regulate their affect (Rochat 2001; Stern 2018), very little research has examined the precise role of experiencing mutually shared positive emotions. Some have argued that this shared experience of positive emotions is also critical for attachment and well-being (Broesch and Carpendale 2021).

**Early forms of communication allow early learning:** Even newborn infants are drawn to the unique features of a human face (Rochat 2001). Very early in life, infants show a preference for human face configurations, their mother's voice, and dynamic and high contrast features such as the eyes and mouth of a human face. This early preference springboards social interaction with the caregiver and others as the infant experiences

the caregivers' gaze from birth and soon after, the infant gazes back. This early dyadic interactive behavioral system leads to other more complex forms of communication later on as the infant and caregiver learn to anticipate and respond to one another. Adults also aid in language learning even in the first moments of life. Adults speak to infants in a modified manner – adjusting the acoustic and prosodic qualities of their speech (Snow and Ferguson 1977). Adults and older children speak to infants more slowly than to other adults, using a higher and more variable pitch (Broesch and Bryant 2018). It is thought that this may aid in language learning or draw the attention to the caregiver and facilitate and support this affective human bond. There is also cross-cultural evidence indicating that parents across diverse cultures engage in modifying their speech to address infants, compared to addressing adults. This is referred to as infant directed speech (IDS) or motherese. Infants are born into a communicative system in which they produce signals and caregivers respond to them. One idea that has been proposed is that this system facilitates efficient and rapid transfer of cultural information, knowledge, and skills. This is referred to as the theory of natural pedagogy (Csibra and Gergely 2009). Evidence for this theory lies in infants' ability to receive subtle pedagogical cues from others as well as caregivers' tendency to produce these cues. These subtle behaviors such as pointing, eye gaze, and infant directed speech highlight relevant information to infants and draw their attention to specific moments or features in a learning situation. They allow efficient and high-fidelity transfer of cultural information.

**Learning through locomotion:** The continuing development of locomotion helps children acquire the ability to adapt to the physical and social environment. The explosion of motor skills in the first year of life helps infants gain new opportunities for interacting with the environment in increasingly complex ways (Adolph and Robinson 2015). As infants develop the ability to sit, crawl, and walk, these changes provide infants with new learning opportunities to interact with objects and their caregivers. Research suggests that achievement of new motor milestones may

facilitate the development of language, later cognitive ability, and concept formation (Gonzalez et al. 2019). Despite the existence of motor milestones, these stages are not fixed and are influenced by the interplay between the child and their environment. In the process of adapting different social and cultural environment, children promote adaptive action responding by their social partners, during their daily routines. The widespread variability in the timing and sequence of motor milestones between cultural groups suggests that motor development is a complex interaction process of biological aspects with environmental influences and experiences. The process of motor development during infancy involves patterned neural activity, perception, cognition, and social interaction. The development of locomotion, therefore, presents infants with new opportunities to discover and practice general principles and mechanisms that are essential to relevant developmental changes.

**Triadic engagement allows referential communication (joint attention):** Human forms of communication are unmatched in other species (Tomasello and Rakoczy 2003). Although other species communicate in complex ways, the recursive nature of human communication is unique. Humans communicate about the unseen, the imagined, the past, and the future. To allow for this, one must be able to represent the ideas of another in the mind. There are several theories existing for human communication and most of them rest on humans' remarkable and unmatched ability for triadic communication and joint attention. Infants begin communicating through crying and, only a few weeks later, they are able to smile in response to a social interaction by producing the first social smile. By the 12th month of life, they have started pointing and uttering their first words. By 18 months, they are amidst a vocabulary spurt. Joint attention occurs when the child and the caregiver are mutually attending to the same thing and they are aware of each other's attention. They demonstrate this through gazing back and forth between the social interactive partner and an object of interest (Tomasello and Farrar 1986). This kind of communication indicates a recognition and a desire to attend to and enjoy

the same thing. This kind of communication is thought to facilitate or even springboard language development.

**Learning from others: Imitation and social referencing.** From early in life, infants imitate others (Meltzoff and Moore 1999). Humans are unique in the extent to which they imitate others (Nielsen and Blank 2011). Not only do infants imitate the emotional expressions of others, but they are also sensitive to the sequence of behavior. What is interesting, however, is that around 18 months of age, infants will start to imitate the intent behind a behavior and not just the behavior itself (Gergely et al. 2002a). This indicates that they have begun to move beyond the observable behavior of their social interactive partners and instead identify the intention underlying the observable behavior, and act on that accordingly. Interestingly, around this age (15–18 months), infants also begin to use others as a social reference, meaning that when an infant encounters an uncertain situation, they refer to the caregiver and modify their response depending on the emotional response of the caregiver (Cohn and Tronick 1989; Carver and Vaccaro 2007). Not only are they using the emotional cues of others to alter their behavior, they are learning critical information about the safety and function of the world. All of this suggests that they are learning important communicative skills and culturally relevant information for survival and success, as early as the first year and a half of life.

**Cultural variation in parental responsiveness:** Although we see striking similarities in the kinds of behaviors parents produce with infants (Broesch et al. 2016), there are significant differences in the selectivity of the response as well as how parents respond to and subsequently shape children (Kärtner et al. 2008). One research group examining cultural variation in caregiving responses to infants proposed a model of development that takes into account cultural variation and results in diverse developmental pathways (Greenfield et al. 2003). Under this model, parenting goals (as a result of societal pressures and the ecology) which parents are not always aware of – shape parenting behaviors – both subtle behaviors in interactions with infants and more overt or

explicit choices parenting older children. These different parenting styles can be considered or referred to as collective or individualistic – interdependent or independent cultural lifestyles. Although each society and family has elements of both, the position of the self in relation to others is what determines behaviors in either direction or pathway. We see differences emerge as early as the first few months of life with mothers engaging with their infants and interacting in different ways. Mothers in more independent societies typically engage with infants with face-to-face interactions but with a little touch. In more interdependent societies, mothers engage with more holding and touch and are in close proximity to infants. Responsiveness (which is deemed critical for attachment, but also for shaping social expectations of behavior) is also different depending on parenting goals within and between societies. Mothers respond using touch or face-to-face stimulation. We also see differences in object exploration and communication – suggesting that early forms of triadic interaction vary across cultures (Little et al. 2016). All of this is to suggest that indeed there are foundational elements of the human experience that are critical for healthy, typical development; yet, there are rich social differences that depend upon a milieu of factors, and these differences shape the developing child. Culture acts as a filter, shaping the output of parental behavior and hence a child's early social experiences.

**Referential communication: Gestures and Language.** In the second half of an infant's first year of life, they begin producing and responding to gestures and other nonverbal cues such as pointing (Kettner and Carpendale 2018). These gestures are typically learned through social interactions and daily routines with caregivers (Kettner and Carpendale 2018). Eventually, once mastered, they allow the infant to communicate with others by referring to objects and engaging in triadic communication using symbolic gestures and referents. This ability allows humans to communicate about forms that are not in the present or directly in view. For example, these forms that human can communicate about are things such as the mind – internal feelings, thoughts, and

perspectives. Keep in mind that these feelings, thoughts, and perspectives often require communication to be symbolic. This unique ability for symbolic communication, in combination with the pedagogical system, allows humans to learn culturally relevant information from other individuals.

## Human-Animal Interaction

Elise R. Thayer and Jeffrey R. Stevens

Biology and Behavior, University of Nebraska-  
Lincoln, Lincoln, NE, USA

### Definition

Human-animal interaction captures the mutual and dynamic exchanges between humans and other animals and their psychophysiological effects on humans (Griffin et al. 2011). Types of human-animal interaction include affiliative interactions (e.g., pet ownership), animal-assisted interventions, and service animals.

### Introduction

Contact between humans and other animals – human-animal interaction (HAI) – involves the mutual and dynamic exchanges between people and animals and their psychophysiological impact on individuals (Griffin et al. 2011). Though originally focusing on cardiovascular benefits of companion animals, researchers from a host of scientific fields – ranging from clinical and experimental psychology to public health and veterinary medicine – have demonstrated a wide range of positive effects of HAI on human health and well-being. A taxonomy of HAI categorizes it into the affiliative relationships between humans and animals, animal-assisted interventions, and use of service animals for clinical populations (Fig. 1).

### Types of Human-Animal Interactions

The ever-present reciprocal relationships between humans and animals in societies throughout history translate today into both traditional social interactions as well as those catered to the evolving needs of the present day. In ancestral times, humans shared affiliative bonds with animals

**Human-Animal Interaction, Fig. 1** Types of human-animal interactions

through cooperative hunting and companionship. Today, we have integrated animals into human society in novel ways, including bringing them into classrooms and therapy rooms. Although the bulk of HAIs involve dogs, these interactions can involve many other species as well. A number of clinical therapies incorporate horses into treatment plans, for example, and interventions catering to elderly populations employ small birds and fish (Beetz et al. 2012). The nature of HAIs, including the goals and degree of structure and training involved, leads to three classifications: affiliative relationships, animal-assisted interventions, and service animal interactions (Fig. 1).

### Affiliative Relationships

Affiliative relationships between humans and their companion animals, or ► [Pets](#), entail a strong emotional attachment that facilitates the exchange of physical and psychological benefits. Pet ownership correlates with a number of health benefits, such as increased physical activity and lower baseline blood pressure (McCune et al. 2014). Because ownership is a choice, however, it is difficult to establish whether affiliative relationships cause health benefits or people likely to benefit choose to own pets.

### Animal-Assisted Interventions

Animal-assisted interventions (AAI) involve trained practitioners (e.g., handlers, researchers, teachers, therapists) bringing animals into an environment to interact with people for the

purpose of providing psychophysiological benefits. AAIs cover a wide range of interactions, from improving students' reading ability in classrooms to helping stroke victims recover social and functional abilities. As such, the American Veterinary Medical Foundation (AVMA) partitions interventions into animal-assisted activities, education, and therapy (AVMA 2019).

#### Animal-Assisted Education

Structured and goal-oriented interventions aiming to improve educational outcomes are referred to as animal-assisted education (AAE; AVMA 2019). AAEs in primary schools incorporate dogs and small animals (e.g., guinea pigs, rabbits) in programs tailored to typically developing students as well as those with special needs. Reading programs are the most common, empirically supported interventions for typically developing students (Brelsford et al. 2017), but classrooms also house animals to promote students' general concentration, motivation, and relaxation (Beetz et al. 2012). Interventions for students with emotional or behavioral needs use dogs for the same purposes, as well as to improve social and emotional outcomes in the classroom (Brelsford et al. 2017).

#### Animal-Assisted Therapy

Animal-assisted therapy (AAT) requires specific goals for enhancing an individual's cognitive, emotional, physical, or social functions (AVMA 2019). AATs are structured, short-term interactions delivered in therapeutic contexts by professionals in the field. Animals have been used in therapies for children with autism, adults with spinal cord dysfunction, older adults with dementia, and prison inmates (Beetz et al. 2012; Muñoz Lasa et al. 2015).

#### Animal-Assisted Activities

Unlike animal-assisted education and therapy, animal-assisted activities (AAAs) are not exclusive to structured and goal-oriented programs, leading to rich variety in these interactions. AAAs enhance individuals' quality of life and center the animal as a motivational or social tool in an interaction with the aid of a trained

volunteer, paraprofessional, or professional (AVMA 2019). For example, AAAs include having animals interact with college students in de-stressing events (Crossman and Kazdin 2015), elderly populations in geriatric facilities (Souter and Miller 2007), and children during doctor's visits (Beetz et al. 2012).

### Service Animals

Service animals are individually trained to help disabled persons overcome specific disabilities. They promote a more independent livelihood, facilitating, for example, mobility for the visually impaired, low blood sugar detection for diabetics, or support for veterans with post-traumatic stress disorder (PTSD; McCune et al. 2014; Rodriguez et al. 2018a). In the United States, the Americans with Disabilities Act and other federal legislation regulates service animals as those explicitly trained to perform tasks for individuals with disabilities. Animals that also live with individuals and are prescribed by medical professionals to improve health and well-being, such as emotional support animals and comfort animals, are not recognized as service animals because they have not been trained to perform explicit tasks. The Americans with Disabilities Act limits service animals to ► [Service Dogs](#) and small horses (AVMA 2019).

## Effects of Human-Animal Interactions

The variety of possible types of interactions that occur between humans and animals results in an equally rich variety of effects on human health and well-being, including behavioral, educational, physiological, and/or psychological effects.

### Behavioral

HAIs seem to strongly influence social behavior, perhaps due to the social nature of the interactions. All HAI types promote social interaction. Affiliative interactions resulting from child pet ownership, for example, promote positive social interactions, autonomy, and responsibility and decrease aggression (Purewal et al. 2017). The explicit goal of many AAIs is to facilitate social

interactions, such as therapies for autism spectrum disorders, dementia, or intellectual disability (Muñoz Lasa et al. 2015). Service animals facilitate social interactions as well, demonstrated by disabled persons experiencing more positive social interactions when their service dog is present than without (Beetz et al. 2012).

### Educational

HAIs, most commonly AAIs, provide motivational, social, and emotional benefits to students across all levels of education. Primary education classrooms use dogs to promote a range of behaviors to improve their experience and performance (e.g., concentration, motivation, relaxation) in classrooms generally as well as through reading and behavioral programs (Brelsford et al. 2017). AAIs on college campuses, on the other hand, cater explicitly to relieving exam-related stress (Crossman and Kazdin 2015). These stress-relief sessions, where students interact with animals for short periods of time at their will, occur outside classrooms on campuses to reach a large number of students.

### Physiological

The physiological effects of HAIs relate to stress, bonding, and physical activity. The physiological benefits of HAI can be direct, such as decreased blood pressure, or indirect, such as with increased levels of the hormone oxytocin in bonding.

### Stress

Long-term affiliative interactions can influence cardiovascular measures associated with physical health (e.g., blood pressure, heart rate, heart rate variability). In individuals with cardiovascular disease, for example, pet owners have lower mortality than nonowners (Schreiner 2016). In healthy populations, pet ownership correlates with lower heart rate, lower blood pressure, and faster stress recovery (Schreiner 2016). AAIs also elicit cardiovascular effects, where the intervention mediates cardiovascular responses to short-term stressors. These shorter-term interventions aim to reduce stress in doctor's offices, before dental procedures, and in laboratory settings (Beetz et al. 2012).

HAI influences skin conductivity, or electrodermal activity (EDA), a measure associated with emotional arousal (Rodriguez et al. 2018b). Fiocco and Hunse (2017) introduced a dog following a stressful event, for example, and individuals with the AAI showed lower electrodermal activity than those without, suggesting the intervention reduced their stress response.

HAI also affects cortisol, a hormone shown to increase in response to short-term stress, such as cognitive challenges, and long-term stress, such as depression (Schreiner 2016). Studies with both pets and AAIs show decreased levels of cortisol in the saliva following brief interactions, whether under stressful or normal conditions (Beetz et al. 2012). Service animals also affect cortisol levels, such as in veterans with PTSD who have service dogs (Rodriguez et al. 2018a).

#### Bonding

HAI influences other hormones related to social behavior. Oxytocin, a hormone and neurotransmitter that promotes social bonding, responds to interactions in both humans and the animals involved. When pet owners physically contact or look into the eyes of their dogs, oxytocin levels in their blood/urine increase in both owner and dog, an effect observed in AAIs between humans and unfamiliar dogs (Beetz 2017).

#### Physical Activity

Physical activity is a critical component of human health linked to decreased cardiovascular disease, diabetes, and other illnesses. Dog owners are more likely to meet national guidelines for physical activity (McCune et al. 2014). The physical activity that dog ownership requires (e.g., dog walking) is mutually beneficial, ensuring active lifestyles for both the owner and the animal. There are also animal-assisted interventions that facilitate physical activity, namely, for disabled individuals. For example, there are AATs for those with nervous system impairments to improve balance, limb-control, and walking (Muñoz Lasa et al. 2015).

#### Psychological

Human-animal interactions of all types elicit positive psychological effects in clinical and

nonclinical populations across the lifespan. Pet owners are less lonely, depressed, and anxious, though the risk of extreme grief due to pet loss should not be overlooked (Schreiner 2016). AAIs can not only improve general mood (Beetz et al. 2012), but they can reduce symptoms of emotional disorders such as depression (Souter and Miller 2007) and anxiety (Beetz et al. 2012) and behavioral disorders such as attention deficit-hyperactivity disorder and autism spectrum disorders (Busch et al. 2016; Muñoz Lasa et al. 2015). Medical professionals prescribe individuals emotional support animals to mitigate these symptoms as well.

## Conclusion

Humans have interacted with animals for millennia, and these interactions are becoming more common in our daily lives. Because of the rise in the frequency of these interactions, a broad research effort exists to investigate how these interactions improve human and animal health and well-being. More collaborative scientific research is vital to grow and establish a theoretical understanding of the reciprocal relationship between humans and animals observed across the lifespan.

## Hunting

Sarah Banet-Eugene and Joseph Taylor  
Oxford Brookes University, Oxford, UK

### Synonyms

Trapping; Sporting

### Definition

Hunting can be defined as the pursuit of wild animals with the intent of killing or trapping them.

### Introduction

Up until the mid-twentieth century, it was widely accepted that the earliest of hominids actively hunted wild animals for sustenance and that these animals made up a significant proportion of their diets. This widespread view was questioned by Richard B. Lee who played a major role in theorizing that this was not necessarily the case for all hominids, particularly those existing in more temperate latitudes. Following 15 months of fieldwork in 1968, Lee demonstrated the reality of a largely plant-based diet in the !Kung Bushmen, a marginalized group which inhabits the semiarid Kalahari deserts of Botswana. Lee suggested that it was reasonable to consider the possibility that the prehistoric “hunter” diet was reflected in that of the !Kung Bushmen’s, which was made up of between 30% and 40% meat.

In the late 1980s, Lee’s hypotheses were confirmed through the development of more sophisticated archeological and taphonomic techniques (Speth 1989). These developments lead to re-examinations of some of the most principal sites on which some of the earliest hunting hypotheses were based on. These analyses challenged the widespread consensus that hominids existing in the Pleistocene period were the fierce, large-game hunters that they were traditionally

believed to be. More likely, they were opportunistic omnivorous scavengers who acquired meat in the form of game abandoned by other predators (Binford 1986; Speth 1989).

In 1976 Robert Andrey, an American paleoanthropologist, proposed the “hunting hypothesis,” a fundamental theory which prioritized the role of hunting in the evolution of the genus *Homo*. Andrey’s hunting hypothesis suggests that the act of hunting leads to bipedalism, the production of tools made from stone or bone, and, eventually, the use of fire. *Homo erectus*’ active hunts are believed to have been the catalyst for language acquisition and the formation of religion and various cultures (Hewes et al. 1973; Narr 2008). Following the innovation of hunting tools, active hunting of wild animals persisted as the sole means to a source of a protein-rich meat until approximately 11,000 years ago when animals were first domesticated (Zeder 2012). Despite the domestication of livestock, hunting wild animals has remained a significant and reliable resource in many areas of the world where they are relied upon for their pelts, furs, hides, and leather for clothing and bones and sinew for tool making and as a source of protein.

Historically, overhunting has played a major role in the changes of the Earth’s ecosystems by disrupting the balance of biological interactions. The Holocene epoch is currently experiencing the “sixth extinction,” which has been ongoing for at least the last 11,700 years, since the most recent Ice Age. Overhunting has been a prominent driving force of this mass extinction, particularly for megafauna existing outside of Africa who quickly succumb to these pressures (Lyons et al. 2004). In many marginal climates or impoverished regions, hunting wild animals is still deemed essential for food security, yet the current rates of extraction may threaten ecosystems and human communities (Ripple et al. 2016). Coupling this with global exponential population growth has led to an exacerbation in the reliance that humans place upon wild fauna and the frequency of human-wildlife interactions (Ripple et al. 2016).

Modern-day hunting has evolved due to the prospect of monetary gain and has been further

enabled by the ease of access to firearms. Money can be gained through sport hunting and from the trade of animals destined to be pets and derivatives for consumption or traditional medicine and for use in cultural and religious ceremonies (Bersacola et al. 2014; Ripple et al. 2016). Poverty is a primary incentive for supplying wild animals for such uses. Together, these factors pose serious threats to vast quantities of biodiversity on both a global and location-specific scale (Ripple et al. 2016).

Legal hunting is at the forefront of many international governing bodies' discussions. Sport hunting and trophy hunting are terms which refer to the business linked to hunting wild game for pleasure. It is in particular a widely debated topic, largely because of the inflammatory nature of killing one animal in the efforts of conserving a population of others. Unfortunately, sport hunting is often subject to corruption and improper management (Lindsey 2008). Such ineffectiveness has led to quotas being exceeded, which threatens species population numbers. To add, poorly managed hunting practices have likely weakened the gene pool for future generations since the individuals with the most desirable characteristics, whether it be the biggest tusk in the case of elephants or the most impressive mane in the case of lions, are likely the carriers of the highest-quality and evolutionary fit genes (Knell and Martinez-Ruiz 2017). Moreover, a lack of reinvestment in conservation and local development has been recognized and has stunted the potential success of these conservation tactics (Crosmar et al. 2015; Ripple et al. 2016). Despite this, properly managed tourism and trophy hunting has been recognized as a potentially suitable method of conserving wildlife in national parks where alternate efforts have in the past been unsuccessful (Crosmar et al. 2015). Furthermore, trophy hunting has proven to be a useful tool in local development by providing jobs and in enhancing the value placed upon wildlife at a local level, thereby decreasing poverty levels and increasing a willingness to conserve wild fauna (Nelson et al. 2013).

Illegal hunting, referring to any hunting or extraction of wildlife unauthorized or prohibited

by state, is widely practiced as deterrents to such activities are inherently weak. Prosecuting, levying suitable fines, seizing goods, recouping proceeds obtained as a result of criminal activity, and issuing prison sentences against lawbreakers not only punish the offender but can also serve as an effective deterrent to other members of the society who may consider offending (Nijman 2017). This too should be the scenario when taking action against criminals who inhibit the success of species conservation – effective law enforcement has the potential to benefit species conservation tremendously (Du Saussay 1984). For example, Sierra Leone, a nation recognized as one of the world's most important biological hotspots most affected by poverty (Fisher and Christopher 2007), still prosecutes offenders based on an outdated Wildlife Conservation Act from 1972. The Act, for example, states that the hunting of prohibited animals, such as elephants (genus: *Loxodonta*) with tusks of a combined weight of less than 5 kg, is punishable by nothing more than a fine of up to Le100 (<\$0.01), up to 6 months in prison, or a combination of both a fine and imprisonment, for the first conviction. These repercussions are too lax to serve as a sufficient deterrent for hunters.

The IUCN (2019) recognizes hunting or trapping as a threat to 3673 of the 27,000 plus species that have been surveyed. Hunting, coupled with the other copious levels of anthropogenic pressure placed upon animals, poses severe consequences to a number of species and subspecies. For example, 2018 saw the northern white rhinoceros (*Ceratotherium simum cottoni*) reclassified as functionally extinct, with the passing of the last known male of the species as a result of exploitation for wildlife trade (Smith 2018). A number of initiatives need to be put in place to combat both illegal overhunting and poorly managed or corrupt legal hunting, as well as other factors that inhibit species success and conservation efforts. Poverty alleviation and food security, education, and inherent value placed upon wildlife are three crucial sectors that need to be combated to alleviate the pressures exerted upon wild fauna (Reynolds and Bettinger 2008).

## Hunting for Bushmeat

Bushmeat refers to wild, undomesticated game that is hunted and later consumed by humans. Due to growing human populations, the dependence placed upon bushmeat has amplified tremendously over the past few decades, exerting increased pressure on wild animal populations, with terrestrial mammals in particular suffering significantly (Ripple et al. 2016). Hunting wild animals for food consumption is one of, if not, the most prominent reasons that people resort to hunting (Ripple et al. 2016). Bushmeat hunting is a contributing factor to the epidemic of species population decline with an estimated 301 terrestrial mammal species being recognized as being vulnerable to extinction (Ripple et al. 2016). Despite being a global issue, populations of wild animals existing throughout areas of South Asia, Africa, and South America are declining at an unprecedented rate (Ripple et al. 2016).

Ease of acquisition is a contributing factor in the popularity of bushmeat. In Central and Western Africa, bushmeat is sold at the side of the road or is often taken to vast markets in cities where it has the potential of yielding a more profits (Bersacola et al. 2014). In Cameroon, for example, Wilcox and Nambu (2007) highlight that bushmeat can be found in rural areas, to be significantly low-cost compared to the alternative sources of protein available in the adjacent town. Although hunting for household consumption may in some cases be locally sustainable, the level of extralocal demand associated with the commercial trade of bushmeat is typically far greater than the forests can support (Bennett et al. 2006). The global bushmeat hunting crisis is particularly alarming since it is intimately linked to local development challenges such as famine and malnutrition and emergent zoonotic disease risks.

Not only is bushmeat hunted in areas unregulated by local authorities, zones designated specifically for the protection of wildlife suffer also. Illegal hunting in protected areas is a major issue afflicting national park's wildlife populations. For instance, migratory herbivores in the Serengeti National Park, Tanzania, have

fallen victim to hunters, resulting in drastic population declines (Loibooki et al. 2002). Following agriculture, bushmeat is considered to be the most important means of generating cash flow in the Serengeti National Park, with estimates of anywhere between 52,000 and 60,000 individuals participating in illegal hunting within protected areas each year (Loibooki et al. 2002). The income generated by the sale of wildlife in these areas has been recognized as not only vital for sustenance but also for paying government taxes and local development levies (Loibooki et al. 2002).

The dynamics of bushmeat hunting and trade can in some areas be dictated by local political influences. For example, the availability of different species at bushmeat markets and the quantities in which they are sold can differ greatly dependent on political tension (De Merode and Cowlshaw 2006). During peacetime in the Democratic Republic of the Congo, endangered and protected species represent more than half of all bushmeat sales in the urban market, and this number only increases during war time (De Merode and Cowlshaw 2006). During times of political stability, the commodity chain is governed by the local army who, despite allowing the illegal hunting of protected species, do regulate the number of citizens allowed to hunt (De Merode and Cowlshaw 2006). In contrast, during times of political instability when the army is transferred out of the local area, lower ranking soldiers take control of the commodity chain and loosen hunting restrictions resulting in an additional influx of protected species entering markets for trade (De Merode and Cowlshaw 2006). In more rural markets however, which are supervised by the local authorities, political instability seems to be an unrelated factor to the species which appear at the market as these authorities impose stricter guidelines (De Merode and Cowlshaw 2006). In both times of political stability and instability, protected species constitute an insignificant proportion of bushmeat traded in rural markets.

In order to reduce the unsustainable bushmeat hunting and therefore increase wildlife conservation, consumers must be educated and be given access to adequate and affordable alternatives

(Reynolds and Bettinger 2008). Reducing the price of livestock and increasing the availability of domestic meat for local consumption would likely reduce the demand of bushmeat (Milner-Gulland and Bennett 2003).

## Hunting and Wildlife Trade

Wildlife trade can be defined as any sale or exchange of wild animals or their derivatives between humans (Wright et al. 2016). Illegal wildlife trade in wild species and products can include different biological resources including rhino horn, elephant ivory, medicinal plants, timber, shark fins, and pangolins scales, to name a few. Poaching and illegal wildlife trafficking has now reached an unrivaled stage. This deprives local communities of conservation- and tourism-based employment opportunities that are dependent on the presence of wildlife as a result of dwindling biodiversity in some areas (Wright et al. 2016). As of 2011, the value of global trade of illegal and prohibited goods was calculated to be worth between \$7.8 billion and \$10 billion per year, ranked just behind the illegal drug trade (Wright et al. 2016).

The lack of ownership and value assigned to wildlife by local communities, coupled with ineffective land use, poverty, food insecurity, and corruption, drives the illegal trade. To illustrate, poaching of the African elephant (*Loxodonta africana*) has risen to a level that threatens the long-term viability of the species (Gao and Clark 2014). Poaching and the associated illegal ivory trade is currently considered to be the most significant threat to the species, requiring urgent, collective, and cooperative action (Gao and Clark 2014). Data shows that poaching has increased from 2006 onwards and rose to an unsustainable level with illegal killing rates estimated to average approximately 6.8% between 2010 and 2012, amounting to approximately 33,630 elephants killed per year (Witemyer et al. 2014). International non-governmental organizations (NGOs) and media often attribute the basic problem to China's domestic ivory market (Gao and Clark 2014). Given the substantial

evidence that is now available, it is undeniable that the current Chinese domestic ivory market is an important driver of poaching and trafficking problem (Gao and Clark 2014). In China, the possession of ivory is a sign of wealth, affluence, or importance. Chinese craftsmen use ivory to create smoking pipes, daggers, chopsticks, jewelry, ornaments, souvenirs, and hair accessories. Some Asian nations also highly value elephant tusks for their apparent medicinal properties. If the price of ivory in China remains high, and effective measures are not taken in a timely manner, poaching will continue unabated to the detriment of the species. Any solution requires concerted action and collaboration from all countries concerned. It is vital to regain control of the ivory trade in all markets, especially in China, through effective multi-agency cooperation, regulation, policing, and monitoring. Efforts from NGOs and authorities have greatly improved public awareness of the problem.

Pangolins (genera: *Manis*) are widely recognized as the world's most illegally trafficked mammal. Pangolins inhabit Africa and most of Southeast Asia and are seriously threatened by illegal hunting to supply international trade (Pantel and Chin 2009). The greatest threat to pangolins is illegal hunting for both national and international trade. A large proportion of the pangolins hunted are to supply the extensive demand for their meat and scales used in tonics and traditional medicine, particularly in China (Pantel and Chin 2009). Surveys in China have found that live pangolins and/or their scales are commonly available in open markets. Pangolins are particularly vulnerable to overexploitation, as they are easily hunted, have a very slow reproduction rate, and do not easily breed in captivity (Pantel and Chin 2009). While subsistence hunting of pangolins has likely been prevalent for centuries, large-scale commercial harvesting has boomed in the last few decades, drastically influencing the decline observed in population numbers in the genera.

Primates have been recorded to be among the most frequently hunted group of animals to supply a demand for bushmeat, traditional medicine, and the desire for them as pets (Nijman and Healy

2016; Ripple et al. 2016; Svensson and Friant 2014). The illegal primate trade is known to be a major impediment to primate conservation, especially in Africa (Nijman and Healy 2016; Svensson and Friant 2014). The use of primates in traditional medicinal practices (including *mujji*, more commonly referred to as witchcraft) has been recorded to be on the rise, both in Africa and in Asia. Svensson and Friant (2014) report that 59% of the primate species in Asia and 32% of primate species in Africa are used for these practices. The different uses of primates also seem to differ between regions. For example, hunters in Nigerian local communities report hunting African Lorises for food and medicine and rarely keep them as pets. However, as a result of recent viral media depicting slow lorises (genera: *Nycticebus*) as pets, Western demand for these newly perceived charismatic species has increased dramatically (Nekaris et al. 2013).

Measures to combat illegal trade are advancing, especially in the countries most affected by poaching activities. Law enforcement and conservation education in local communities to enhance sustainable livelihoods are the most promoted actions (Cooney et al. 2017). Cooney et al. (2017) made the reasonable assumption that for wildlife conservation to prevail over poaching activities, one of the essential conditions is that local communities benefit from being involved in wildlife conservation and that this engagement should provide greater benefits than those gained from illegal trade activities. Positively shifting the perception of conservation engagement by the concerned local communities serves to ensure their commitment and empowerment (Cooney et al. 2017), which in turn reduces the allure of illegal hunting. For example, conservation education such as workshops with communities, including targeted interventions, motivates the members of the communities to see the value in wildlife and start protecting the animals around them on their own accord while still obtaining benefits from wildlife resources (Cooney et al. 2017). Furthermore, adequate and powerful forms of enforcement can focus on motivated community members to feel included to protect wildlife and therefore become active partners in combating

illegal wildlife trade (Cooney et al. 2017). In this model enforcement plays a critical role as it upholds and protects the rights of individual community members, rather than potentially undermining them (Cooney et al. 2017).

## Hunting for Sport

Many national parks are currently under funded by governments, resulting in inadequate protection of native wildlife, enabling both illegal and poorly managed legal sport hunts to perpetuate. Some conservationists do, however, suggest that sustainable and well-managed trophy hunts can be a viable option to acquire necessary funding to protect endangered wildlife within those national parks. The premise of trophy hunting is that a permit is obtained that allows the participant, often a wealthy ecotourist, to track, hunt, and eventually kill charismatic fauna, whereby some of the monetary profits acquired from the lucrative sale of the permit is supposedly returned to conservation programs and local community development efforts. In some scenarios the sale of hunting permits is seen to be essential to the conservation of a whole community of wildlife within a protected range. However, mismanagement can jeopardize the feasibility of trophy hunting as a conservation tool and therefore exacerbate the hunting pressure exerted on highly sought-after species. This mediocre handling can be the result of a poor reinvestment of the trophy hunting proceeds into conservation and local community development.

Another issue regarding the sustainability of trophy hunting is the lack of long-term monitoring indicating whether or not hunted populations are still stable and therefore whether or not current management of the trophy hunting is appropriate. The resilience of wildlife populations to trophy hunting is considered to be species-specific. Wide-ranging species with low reproductive rates and sophisticated social structures are generally those most appealing to trophy hunters and are often keystone species to their respective ecosystems (Crosmary et al. 2015). Unfortunately, many species with the aforementioned

characteristics are classified as endangered on the IUCN Red List, and populations could quickly decline to an irreparable number if hunting is improperly managed. This status however has an intrinsic appeal to many hunters who are keen on hunting a “rare” and “alluring” species, which results in an inflated price to acquire a hunting permit for the species (Crosmarý et al. 2015). Contrastingly, hunting pressures can favor the survival of “less-desirable” species, or individuals within a species with less-appealing characteristics than another member of its group. For instance, Crosmarý et al. (2013) investigated the influence of trophy hunting on horn size for antelope in Africa. Longer horned individuals were preferred by hunters resulting in a relatively high hunting pressure expended on sable antelopes (*Hippotragus niger*) along with a higher valued price tag, compared to a relatively low hunting pressure in impalas (*Aepyceros melampus*) and greater kudu (*Tragelaphus strepsiceros*). Over time the hunting and killing of large-horned sable antelopes has resulted in an evolutionary response, with horn length having been found to have decreased.

One of the most dramatic downsides of the high market demand for rare and endangered animals is that these species are usually the least capable of withstanding any additional anthropogenic pressures. For example, the management of wild lion (*Panthera leo*) trophy hunting differs depending on country legislation, and therefore its conservation outcome also varies. Lion populations and their ranges in Africa have decreased considerably in the past 30 years. Nelson et al. (2013) estimate that 30% of lion populations have perished since 1970. Lions are among one of the most economically valuable species in Africa’s trophy hunting market mainly due to its charismatic perception by the general public. Recent debates regarding the lion trophy hunting industry focused on restricting trophy hunting as a measure to address concerns about excessive offtakes of lions which threaten its conservation status.

Tanzania, Southern Africa (including Zimbabwe, South Africa, and Namibia), and Kenya all boast an important lion population, and trophy

hunting occurs in all three regions. Tanzania hosts the second largest trophy hunting industry in Africa and holds four of the six remaining wild lion populations, with over 1000 breeding individuals recorded. Lions are particularly important to Tanzania’s hunting industry because, in contrast to nearly all neighboring countries, lions are legally included in the quotas assigned for the majority of hunting permits. Income generated by lion hunting is particularly lucrative as individual lions can bring in around \$70,000 (Nelson et al. 2013).

Furthermore, in Southern Africa trophy hunting accounts for 84% of annual revenue, by far dominating other regions in Africa. It also has a unique shared regional experience of adopting a number of important wildlife management and policy reforms that have led to wildlife recoveries across large areas of both private and communal land. Economically, trophy hunting can be significant. It makes up around 14% of the whole tourism industry in Namibia, which represents 2.3% of the total Namibian economy. The offer of hunting experiences for upper-income recreational hunters, mostly from Europe, is an important part of the Namibian tourism industry. Trophy hunting in Namibia is controlled both by government and private agents and is allowed on both private and public land (Humavindu and Barnes 2003). In 2000, an estimate of 13,310 game animals were shot by an estimated 3640 hunters, of which 84% were European tourists (Humavindu and Barnes 2003).

Finally, in Kenya hunting has been illegal since 1977; therefore it is the only African country with a population of over 1000 lions that does not presently allow any licensed trophy hunting. Despite the ban on trophy hunting, wildlife conservation efforts in Kenya have been recorded to be prominently unsuccessful (Nelson et al. 2013). Lion populations have declined by 60% to 70% since the 1970s in state protected areas and on communal lands. Lions in Kenya, although not subjected to any legal hunting, are rapidly declining because of human-wildlife conflict interaction and with consequence of killing through poisoning or other means, loss of habitat, and depletion of prey (Nelson et al. 2013). In these cases, it can

be interpreted that trophy hunting can provide conservation benefits for lions when well managed or alternatively constitute a significant threat when governance of the industry is poor (Nelson et al. 2013). The hunting of elderly, ostracized male lions who have already met their biological purpose of passing on their genes could still yield huge profits to benefit conservation and local development, without restricting the gene pool at all.

## Human-Wildlife Interactions

The margin separating the proximity of which humans and wild animals exist is shrinking on a daily basis. Humans are persistently encroaching on vast quantities of land once populated solely by wild flora and fauna as a result of global population growth. As a result, deforestation is occurring at an unprecedented rate in order to secure resources for the human species. Logging, mining, land tenure, and land degradation for livestock purposes are a few of the major activities that continuously disrupt wildlife ranges and the ways in which humans and wildlife interact. As a result of deforestation, natural habitats are destroyed, and areas that were once inaccessible to illegal hunters have opened up, allowing them to pursue wild game in areas in which this was previously unachievable (Chivian and Bernstein 2008).

One of the greatest threats toward humans in a world with an increased reliance placed upon wildlife and a greater likelihood of human-wildlife interactions occurring is the substantial risk for cross-species transmission. The risk of zoonotic disease transmission associated with hunting wild animals for bushmeat and traditional medicine is a topic of increasing interest to public health officials. One of the biggest issues with associated with zoonotic disease is that the animals react very differently to humans and may at first appear asymptomatic. It is well documented that wildlife can act as a reservoir for pathogens to multiply and later be passed on to humans who come into contact with contaminated bodily fluids. For instance, HIV-AIDS was first

transmitted to humans as a result of exposure to the bodily fluids of chimpanzees (*Pan troglodytes*) in West Africa, most likely during the preparation of their bushmeat (Chivian and Bernstein 2008). Those who ready the animal for consumption are at a disproportionately higher risk of transmitting disease due to the fact that they more frequently cut themselves during preparation. This event was likely the impetus for the global pandemic that is recognized today as HIV-AIDS. More recently, on December 6, 2013, the world's most prolific Ebola outbreak began. It was initiated by a 2-year-old in Meliandou, a small village that lies in the upper Guinean forest region, who became infected with a strain of the Ebola virus after eating contaminated bushmeat (Baize et al. 2014). The disease soon spread to more populous cities with international roads crossing to Sierra Leone and Liberia. The World Health Organization (WHO) was not notified of the outbreak until March 23, 2014, who then on August 8, 2014, proclaimed the epidemic to be a "public health emergency of international concern" (WHO Ebola Response Team 2014). By September 14, 2014, cases of the Ebola virus had been recorded in Guinea, Liberia, Nigeria, Senegal, and Sierra Leone (WHO Ebola Response Team 2014). The outbreak resulted in 28,616 cases and 11,310 deaths being recorded across the 3 most prominently affected countries (Guinea, Liberia, and Sierra Leone) (CDC 2016).

## Conclusion

The need to resolve the issue of global defaunation cannot be emphasized enough. Humans place a great deal of reliance upon wildlife and their resources. Thus, hunting plays a critical role in various cultural and economic pursuits for humans in both undeveloped and developed regions around the globe. The practice of hunting has become deeply rooted in many families' traditions and even extends to culture and religion. While remaining sensitive toward these traditions, and the facts that hunting can play a major role in food security, revenue generation, and local development, unsustainable hunting

practices will inevitably result in the loss of species, and a disjointed ecosystem will follow. Governance of hunting is weak and/or inadequate in many countries. The promise of community-based, devolved wildlife management models remains in most cases tantalizingly unrealized, while “top-down” models of centralized command and control often offer little promise of long-term sustainability and/or ignore or override indigenous or local rights and livelihood needs. Despite the necessity that we as humans place upon these animals, the need for collaborative, multifaceted, and environmentally stable models is pertinent.

While sustainable hunting, particularly for bushmeat, alleviates the atmosphere of greenhouse gases produced by the most common alternative, farm-bred animals, the future of some wild species victim to persistent overhunting is bleak. Most notably, species with long-life histories are those most susceptible to unsustainable hunting practices such as orangutans (genera: *Pongo*), chimpanzees, and elephants (genera: *Loxodonta*).

It is unrealistic to expect hunting of all wild animals to one day be completely abolished. However, the continued offtake of game can only be sustained for as long as hunting-induced mortality of any subjected species is exceeded by production (Fa and Peres 2001). Therefore, strict regulation and management is crucial to the survival of our most cherished species. Furthermore, outreach is needed to educate the public on the implications of speciation loss and the zoonotic threats that wildlife poses to humans. In order to be as effective as possible, efforts must incorporate culturally accepted practices (Reynolds and Bettinger 2008).

Texas A&M College of Veterinary Medicine and Biomedical Sciences, College Station, TX, USA

## Synonyms

Animal care; Animal management

## Definition

Historically, animal husbandry was a term used to define the agricultural practice of raising

livestock. Its modern usage has evolved to incorporate all animals in human care, including exotic animals and companion animals. Husbandry can be described as the proper management and care of animals, including the regulation of water, food, environment, and breeding.

## Introduction

Although the term “husbandry” did not appear in the English language until the early fourteenth century, the discipline of animal management has been in practice for roughly 11,000 years (Vigne 2011). The domestication of livestock and development of a stock keeping system marked a monumental transition point in the evolution of the human lifestyle. The invention of this type of agricultural operation allowed for a more sedentary existence and eventual abandonment of the hunter-gatherer system, leading to the development of modern society. Over the centuries, the degree of human involvement and intensity of these management systems have gradually increased, with occasional spikes in activity as new species are domesticated or new technologies invented. Today’s animal husbandry methods are some of the most intensive to date, taking into consideration every aspect of an animal’s signalment, diet, environment, health, and breeding.

Good husbandry practices are a critical component of animal ownership. Despite the monumental strides taken to raise standards of care in the last 50 years alone, there is still much to be learned. Poor husbandry is still one of the leading causes of illness in certain species (Tully et al. 2012). Not only is husbandry one of the largest factors related to health and quality of life, but it also plays a role in several other controversial subjects. In agriculture, for example, the quality of animal husbandry is positively correlated with the efficiency of resource conversion. Therefore, management improvement leads not only to a higher production value, but also makes modern farming and ranching more environmentally sustainable. In fact, from 1994 to 2007, advances in technology and husbandry techniques resulted in a 59% increase of milk production in US dairy

farms while using 64% fewer cows (United States Department of Agriculture and National Agricultural Statistics Service 2010). In a time where excessive meat consumption has been accused as a source of significant greenhouse gas emissions (IPCC 2014), the importance of this effect cannot be overlooked. Good management also reduces the cost of agricultural products to consumers and improves food security and food safety. Another example of husbandry’s role in society relates to the controversy of using animals for research purposes. While the validity of the animal model continues to be hotly debated, it has been demonstrated that animals that are better cared for produce more accurate and reliable research findings (Prescott 2017). Regardless of one’s involvement in the animal care industry, the effects of animal husbandry continue to be pervasive in our everyday lives.

Of course, the major issue pertaining to husbandry still revolves around the ethics of animal use for human gain. Due to changing ideals and a greater respect for nonhuman life, there is a sweeping trend in today’s society to question the morality of animal exploitation (Fraser 2001). This is true for all animals in human care, whether they are being raised for meat and goods, in captivity for educational or conservation purposes, or being used for research. Some animal rights activists even go so far as to say that pet ownership is a form of captivity, as it restricts the free will of the animal. This scrutiny has necessitated the strict examination and improvement of common husbandry practices and in many cases, improved publicity of these practices.

## The Basics

The first aspect of animal care that should be addressed in a good management system is water. Water is the most critical nutrient in any diet and can be withheld for the least amount of time. In well-developed countries with quick access to running water, this necessity is easily oversimplified. Good management systems, however, take into account many considerations regarding the presentation and quality of the

water being delivered. Regular inspection of water sources should be conducted, ensuring that the water is free of pollutants and debris. In climates where standing water basins may freeze, thermoregulatory systems such as heated buckets should be employed. It is also necessary to regularly check the amount of water consumption that is occurring. For a single animal or a small group of animals, increased or decreased water consumption may be an early warning sign of disease. In larger herds or colonies where it may be more difficult to detect these subtle changes, monitoring is still an important component for detecting larger problems with the water delivery system. Some species may require extra considerations regarding the presentation of water. A good management system will ask questions such as, "Does this species or individual prefer flowing or running water?" and "Where is the best location for the animal(s) to be able to access water easily and comfortably?" An example of a specialized water delivery system is the pressurized spigot/water nipple system commonly employed when raising sows and piglets, which allows them to get clean water at an appropriate rate. In instances where an animal is not drinking sufficient amounts of water without any evidence of disease, it may be indicated to supplement the water with veterinary-approved flavorings, a practice commonly employed with horses. Although water may seem like one of the simpler aspects of animal management, the importance of this nutrient requires that it is never overlooked.

Another fundamental component of animal care is diet. Unfortunately, this aspect is far more complicated than a supply of fresh, clean water. Proper nutrition means something different for each species, life stage, and health status. Each diet should be formulated based on the specific needs of the animal, oftentimes requiring evaluation by a professional. In general, a good diet will consider the natural history and physiology of that species, the known requirements for each of the major nutrients, and research supporting the use of that diet. These considerations vary widely between species (and sometimes individuals within a species) and must be evaluated on a case-by-case basis. For example, despite the

relative similarity of cats and dogs in the grand scheme of the animal kingdom, feeding a diet that is intended for dogs to a cat could cause numerous detrimental health impacts because of cats' significantly higher requirement for protein (Zoran 2002). Adequate nourishment plays a significant role in animal health, resulting in lower instances of disease, a longer lifespan, and higher rates of production and fertility (Shepherd 2014). In some agricultural practices, low fertility rates are a common reason for a cow to be culled from the herd (Hersom et al. 2015), meaning that a good diet could actually be the difference between life and death. Nutritional intervention is also a commonly used medical management technique in certain diseases, such as the breakdown of struvite uroliths, a type of urinary stone, in canines (Lulich et al. 2016). Outward signs of a good diet may include softer coats, less dandruff, or neater feathers. In agriculture, this equates to a higher quality, and therefore value, of products such as wool or meat. When formulating a diet, the amount and frequency of feedings is an important factor. While some animals, like certain types of snakes, may only eat a meal once every few weeks, natural grazers such as horses do better on smaller feedings several times per day. Young animals also need to be fed much more frequently, and neonates may need their meals as often as every few hours. The feedings should be proportioned based on the metabolic demands of that animal or herd, as feeding too many or too few calories can lead to obesity or malnutrition, respectively, each of which comes with its own set of secondary health concerns. It is important to reevaluate a diet whenever changes occur to ensure that the most current information is being used and that the health of the animal(s) is maintained.

Environment makes up another important facet of animal husbandry. At its minimum, good housing will provide relief from extreme heat or cold, shelter from harsh elements, and space for most natural behaviors. Better management systems will also take into account disease mitigation, quality of life, and species-specific requirements. An excellent example of this is the revolution of modern animal habitats by zoos and aquariums.

Where concrete and metal cages used to be the standard, there are now intricate and precisely designed enclosures. Ideally, these enclosures are constructed in a way that allows for the safety of the animals and keepers, the ease of husbandry or medical procedures, and the encouragement of natural behaviors. The best husbandry systems will take a wide variety of factors into account, including the temperature and humidity, ideal type of soil or bedding, the right amount of sun versus shade, the number of trees available to climb or nest in, the types of structures to hide behind or dig under, etc. Again, the necessities for each species vary widely and should be evaluated by someone with extensive knowledge of their specific needs. Disease mitigation is another important factor of enclosure design. It requires consideration of animal density, the types of species that are interacting with each other, and even the air flow and housing materials. In general, a less densely populated environment with fewer cross-species interactions has a lesser risk of disease outbreaks. Air should flow in a way that prevents aerosolized infectious agents from settling in the environment, and materials in the environment should be easily cleaned or replaced. New or ill animals that have the potential to shed infectious organisms should be quarantined from the rest of the group, typically for 28 days. While a well-managed environment may not have the obvious or immediate health implications as that of water or nutrition, it can have enormous impacts on quality of life and psychological state (Wolfensohn and Honess 2005).

In most instances, breeding management is also an important part of animal husbandry. Selective breeding has been used since the domestication of the wolf centuries ago (Vigne 2011), leading to the many different dog breeds we have today. It plays a particularly large role in livestock, where certain qualities are far more valuable than others. Selective breeding can improve the quality and marbling of meat cuts, the rate of gain or size of an animal, the value of products such as hide or wool, and the hardiness of the animal. This prevents undesirable traits such as susceptibility to disease from being passed down to new generations and contributes to the

increased productivity of modern agriculture. Today, breeding management is also an important part of exotic animal conservation. In 1981, the Association of Zoos and Aquariums (AZA) created the Species Survival Plan Program, which allows for the population management of certain species that are of critical status in the wild (Association of Zoos and Aquariums 2017). This process involves the coordination of hundreds of facilities and often involves the temporary transfer of certain individuals to be with their genetically ideal mates (colloquially known as being on “breeding loan”). Careful planning of known family lines and the development of new biotechnologies make it possible to foster offspring that can help maintain the biodiversity of a given exotic population the same way that it can improve the productivity of the modern livestock industry (Renaville and Burny 2002).

## Additional Considerations

Given the overwhelming diversity of the animal kingdom, there is no comprehensive list of the factors a husbandry system must consider to be complete. Each species has additional considerations that must be evaluated. Sometimes even individual animals within a species require special deliberation. It is important to consult the current literature as well as experienced personnel in order to assure that all potential issues have been addressed. In instances where there is limited information available, it is not uncommon to extrapolate data from closely related species, but this method should be used with caution. Additional items to consider may include nail, hoof, or beak trimmings; the harmoniousness of social groupings; the ability to perform natural behaviors; and mental stimulation with enrichment activities (Wolfensohn and Honess 2005).

Zoos, in particular, tend to employ the use of environmental enrichment devices (EEDs), which are toy-like items commonly used to stimulate animals and prevent stereotypic behaviors related to boredom. If EEDs are going to be used, they should first be evaluated for safety (not containing toxic materials, not able to be broken apart or

ingested, etc.) and also for their relevance to the natural behaviors of that species. Other forms of enrichment include the presentation of unusual food items, the deliberate positioning of food in locations that encourage hunting or foraging behaviors, and even music. Training behaviors can also be used to add mental stimulation, help forge a human-animal bond, and also facilitate animal health while maximizing human safety. This method is most commonly performed in zoological environments, where most animals' first training exercises are approximations towards behaviors that facilitate medical procedures, such as taking medications or blood collection. Regardless of the type of animal, good management systems will consider these additional needs and meet them with methods appropriate for that species.

It should be evident at this point that the development and implementation of good husbandry practices is not a one-man job. "It takes a village," as it were, and there are several other sources that should be consulted when establishing an animal management system. As discussed previously, proper nutrition is of vital importance to overall health. In instances where thoroughly researched diets (e.g., well-known commercial pet foods) do not already exist, it would be prudent to hire a nutritionist who has experience working with the given species. Another resource of information that must not be forgotten is the veterinarian. Veterinarians possess additional knowledge that permits them to make clinical judgments regarding the health of an animal and detect illnesses that may have been overlooked by others. They will be able to recommend when treatment is indicated and what precisely that treatment should include. Preventative care is also an important aspect of husbandry, and a veterinarian can advise when certain therapies are necessary, such as vaccinations or parasiticides. Some veterinarians have gone through additional training to become board-certified in various areas of medicine; their expertise may be required when dealing with more complex cases. Note that good record keeping is also an important part of animal health, and thorough documentation should be made of any treatments or therapies administered.

A final resource that should not be overlooked is the body of current literature. Peer-reviewed articles or manuals can provide more in-depth instruction for the specific requirements of the species at hand, the value of which cannot be underestimated. In order to ensure the best quality of care, it is essential that the husbandry team, veterinarian, and any other parties involved work together to develop a comprehensive action plan for animal care.

## Relationship to Welfare

A good state of animal welfare is the direct result of proper husbandry. Just as with humans, good animal care takes into account physical, mental, emotional, and social wellbeing. In recent years, public concerns have drawn particular attention to the welfare of animals, regardless of whether they live on a farm or in a zoo. Unfortunately, there is no formal consensus as to what measurements should be used to evaluate welfare. One of the earlier and certainly most notable attempts to create a systematic assessment is from the 1979 publication of the Farm Animal Welfare Council. It introduced a list that is commonly referred to as the "five freedoms" and includes freedom from hunger or thirst; freedom from discomfort; freedom from pain, injury, or disease; freedom to express (most) normal behaviors; and freedom from fear or distress. Yet even this modest list is not without its complications, particularly when one or more "freedoms" do not coincide. One example of this is the housing of hens in battery cages. While this housing style restricts movement and can induce abnormal behavior (Duncan 2001), it is also associated with fewer instances of diseases (Fossum et al. 2009). Still, others cite physiologic evidence (growth rate, health, and behavior) or subjective experiences (ability to access desired stimuli and absence of avoided stimuli) as a way to measure welfare (Mendl 2001). Despite the many attempts that have been made to determine whether an animal's husbandry is adequate, our evaluations are at best close approximations to what we think they may be experiencing and never the precise reality. For

example, if an employer were asked to judge the welfare of their employees, they might evaluate a number of factors including punctuality, physical appearance, and attitude; however, as we all know, the ability to show up to work looking moderately presentable and exchange pleasantries does not always equate to the pinnacle of welfare. Given that we are by no means experts at assessing the welfare of members of our own species, it is no surprise that we struggle to do the same for our animal charges.

However, definitive standards of care are in place to ensure a minimum level of wellness and in many cases will define “best of care” practices. These husbandry requirements are set by many different groups at various levels of enforcement. Towards the lower end of this spectrum are group bylaws or codes of conduct. Many organizations, including the AZA and the Pet Industry Joint Advisory Council (PIJAC 2017), provide their own set of standards that must be followed in order to be a part of their association. In some cases, governmental entities can also recommend a certain set of standards within their jurisdiction. An example of this would be the counsel and regulation of facilities that house marine mammals at the national (Canadian Council on Animal Care 2014) or local (Ontario Ministry of Community Safety and Correctional Services 2014) levels. In contrast, the Animal Welfare Act (1966) is the only federally enforced law that regulates the treatment of animals in the United States. It is undeniable that without thorough knowledge and implementation of good animal husbandry practices, good welfare would be unattainable.

## Conclusion

Animal husbandry is ubiquitous in modern society. It has a significant role in numerous aspects of everyday life, from pet ownership, to animal welfare, to consumerism. While the debate regarding the utilization of animals for human purposes will likely never end, it is generally agreed upon that adhering to the best known standards of care is hugely beneficial for both animals and humans

alike. With due consideration of proper water, nutrition, shelter, and breeding practices, we are better able to ensure the optimal health and wellbeing of the animals in our care.

## Hybrid

Julianne Wilson  
University of Pennsylvania, Philadelphia, PA,  
USA

## Definition

The progeny of a mating couple from two distinct genetic populations.

## Description

The resulting offspring of two genetically non-identical species is deemed a hybrid. The genetic and/or phenotypic characteristics of a hybrid can be anywhere from a duplication of one parental genus to an even mixture of the two parental species. The hybrid may also be a novel entity without physical similarities to either parent (Evin et al. 2015). Subsequent generations of hybrid breeding can lead to increased genetic and phenotypic diversification and eventual speciation, or the development of a new species (Buerkle et al. 2003).

Some examples of hybrid species include the mule (the F1 progeny of a male donkey and female horse) and the hinny (the F1 progeny of a male horse and a female donkey). Both of these hybrid species are almost always sterile, although there is record of a female mule giving birth after mating with a donkey. The owners of the unlikely foal say it has horse, donkey, and mule-like physical characteristics (Rong et al. 1985).

## Fertility and Viability

Continued hybrid breeding can have varying effects on a species based on fertility and the viability of the hybrids formed. Fertile hybrids can be backcrossed to one parental species to introduce genetically favorable traits and potentially increase the adaptability of the parental species. Hybrids may also interbreed to eventually form a new species. If the genetics of the novel species are more evolutionarily favorable than those of the parental species, one or both of the parental species may become extinct. The novel species, in essence, may replace the parental species as a more evolutionarily robust alternative.

In contrast, hybrid progeny may be infertile or even inviable. Continued unsuccessful mating or production of such offspring can lead to a population decrease of the parental species and threaten extinction if not properly balanced with successful reproduction (Goulet et al. 2017).

## Natural and Artificial Hybridization

Natural hybridization occurs when two unique species successfully mate in the wild without human intervention. At present, natural hybridization is relatively rare; however, genetic testing has shown evidence that hybridization occurred at least once during the evolution of myriad plant and animal species in existence today. It can be beneficial to study some of these occurrences to more-intricately analyze changes in the flow of genes during evolutionary selection (Abbott et al. 2016). Additionally, comparing the genetic similarities and differences between species can help to reveal their relative divergence time (Goulet et al. 2017). Thus, natural hybridization can help to decipher the path of complex phylogenetic trees and allow humans to gain insight into not only how current species have evolved into being but also how they may continue to evolve over time.

Artificial hybridization involves human interference with the mating practices of two species, often by selecting the mating pair that will form the hybrid progeny. The development of hybrid

species through human-controlled hybridization allows for the creation of unique systems that can be considered more biologically advantageous. Humans can use hybridization data to increase the amount of genetic variability and experimentally select for traits most beneficial for a specific purpose. Examples for selected traits include size, disease resistance, diet, and physical appearance (Zhang et al. 2014).

Artificial hybridization, although beneficial, still has its limitations. It can take many generations to observe a distinct difference in phenotypic and/or genotypic characteristics in a hybrid line. The length of time to attain multiple generations can vary from days to decades depending on the organism. Sexual compatibility and hybrid fertility are other obstacles commonly encountered when trying to create a hybrid line. To break through some of these barriers, scientists have developed ways to genetically modify crops using methods such as radiation treatment as well as cellular and molecular techniques (Raybould and Gray 1993). While the use of these techniques is controversial, they allow for new types of hybridization once never thought possible.

## Synonyms

[Heterosis](#)

## Definition

Hybrid vigor or heterosis can be defined as the superiority of F1 hybrid over both the parents in terms of productivity and robustness.

## Introduction

Heterosis can be defined as increase in the vigor that is observed in progeny after mating of diverse individuals belonging to different species or population. It is of immense economic value in the field of agriculture. Heterosis has been harnessed for increased productivity and better livestock that results in crop improvement. Although it is a well-known phenomenon, underlying mechanism still needs to be explored.

## Origin and History of Hybrid Vigor

The phenomenon of heterosis is known for its superior or improved agronomic performance via heterozygous F1 hybrids in comparison to two genetically different homozygous parents. This superiority can be in terms of product yield, biomass, size, fertility, development, and resistance to environmental calamity of any kind when compared to their homozygous parental inbred lines (Hochholdinger and Hoecker 2007). Hybrid vigor is used as a synonym of heterosis. Koelreuter (1763) first reported heterosis in the hybrids of tobacco, *Datura*, etc. Mendel later on (1866) observed this in pea crosses. A long-lasting mystery of hybrid vigor was first described by Charles Darwin (1876) after observing the progeny of cross-pollinated maize (*Zea mays*) which were 25% taller than progeny of inbred maize. Heterosis has been exploited since decades in the field of horticulture and agriculture. It has been a matter of debate, whether it's the genes at multiple loci or the molecular complex inherited pattern behind the underlying cause of heterosis.

A number of enthralling hypotheses are converging toward a consensus explanation incorporating differential gene expression pattern as well as one or more metabolic pathways affecting yield of the crop behind the manifestation of heterosis. With recent advancements in functional genomics, transcriptomics, proteomics, and metabolomics, we end up having clues from genetic, transcriptomic, as well as epigenetic studies (Baranwal et al. 2012).

- (i) **Genetic hypothesis:** According to the genetic model of heterosis, both “dominance” and “overdominance” nonadditively explains phenotypic behavior as a consequence of differences in the genetic component of individual homozygous parents and the hybrid generated. The dominance hypothesis explains the increased vigor of hybrid progeny results due to complementation of superior dominant allele from both the parents at multiple loci over unfavorable allele (Bruce 1910) The “overdominance” hypothesis explains heterosis on the basis

of allelic interaction at multiple loci in hybrids resulting in much superior traits when compared to their homozygous inbred parental lines (Hochholdinger and Hoecker 2007). Recent literature along with genetics reflects the involvement of epigenetics in heterosis.

- (ii) **Molecular hypothesis:** To establish a causative link between heterotic phenotype and the molecular mechanism involved is the greatest challenge faced by many researchers. They proposed a “phenomics” platform where they focused on high-resolution quantitative trait locus (QTL) mapping for measuring multiple traits with the thought of dissecting the fundamental components of heterosis (Lippman and Zamir 2007). It is well known that environment plays an important role in the manifestation of heterosis, so QTLs may respond differently in greenhouse when compared to field conditions. Although various molecular studies showed the involvement of various loci in heterosis, no QTLs associated with heterosis have yet been cloned.
- (iii) **Epigenetic hypothesis:** As heterosis is a genome-wide phenomenon, global genetic and protein expression alterations are not new to discuss. It is very clear that heterosis results from complex interaction occurring inside the nucleus of a hybrid. Besides the interaction of genes from homozygous inbred lines, DNA methylation machinery and its regulatory components would also interact in supporting epigenetic status of heterosis. In the past 3–4 years, global methylation, siRNA distribution, and miRNA expression pattern have been analyzed (Ha et al. 2009). Altered methylation levels were correlated with the transcriptional status of the genes in hybrids. Increasing knowledge of epigenetic signatures provide new prospects to understand the reason for non-inheritance of F1 heterosis traits in subsequent generations (Groszmann et al. 2011).

Still after various heterosis-related studies, one can say genome sequencing of several

genotypes can help in understanding the importance of genomic organization. Differential expression profiling and microarray data of different genotypes and at different developmental stages might help us in explicating inbred lines with the hybrids generated. Data available so far showed no correlation between genetic component and molecular hypothesis related to heterosis. Heterosis is a result of gene diversity, pathways known and yet to be discovered. Not a singular, unifying mechanism can explain the process of heterosis. We should focus on recent and advanced genomic resources to dig out the Mendelian factors involved behind the process of hybrid vigor. It might solve an issue of evolutionary relationship of heterosis and help in crop improvement.

### Introduction: The Paradox

Eusocial insects posed early difficulties for the theory of evolution by natural selection, so much so that Darwin (1859) himself described the dilemma as follows:

...first appeared to me insuperable, and actually fatal to my whole theory. I allude to the neuters or sterile females in insect communities: for these neuters often differ widely in instinct and in structure from both the males and fertile females, and yet, from being sterile, they cannot propagate their kind. (p. 269)

In response to this perceived challenge to his theory, Darwin would go on to provide an explanation for selection occurring at the unit of the *family*, stating that the reproducing morph (e.g., the “queen”) within any given family (the “colony”) serves as the indirect route through which all of the highly specialized, but sterile, morphs (such as the “workers” and the “soldiers”) propagate. Although Darwin evidently believed that this provided an adequate description of the situation, certain theoretical quandaries persisted. Most notably, Darwin’s eusocial insect *family* happens to simultaneously constitute the whole insect *society*, as the entire colony is typically (but not always) of one lineage. Thus, how shall we today construe the action of natural selection on these systems? Can a clear distinction between *kin selection* and *group selection* be drawn?

## Hamilton’s Solution

These issues, among many others, caught the eye of a young W.D. Hamilton, who published his approach to understanding the evolution of eusociality in 1964, called *inclusive fitness theory*. To illustrate his theoretical framework, Hamilton referenced the *Hymenoptera*, a large order of insects in which all of the stinging insects, meaning the *Aculeata* (ants, bees, and wasps), are found, which includes approximately 14,000 eusocial species. Specifically, he discussed their unusual form of sexual reproduction, known as *haplodiploidy*, a process that results in a female wasp having higher genetic relatedness with her full sisters ( $r = 0.75$ ) than with her very own daughters ( $r = 0.50$ ). The proportions of shared genes between her and her full sisters and her and her daughters are represented here by  $r$ , otherwise known as the coefficient of relatedness between two individuals. The female wasp may then, if driven to pass on the maximal number of copies of her genes, aid the efforts of her mother in producing more full sisters, rather than have daughters of her own. Such decisions are what have been presumed to have led to the “sterile” worker caste found across many of these species. In these cases, sterility applies only to the production of diploid daughters, which cannot be done by the worker female, because these individuals do not possess a *spermatheca* for the storage of sperm, and daughters are only able to hatch out of fertilized eggs. On the other hand, haploid sons can sometimes be produced by workers, as they are able to hatch out of unfertilized eggs through parthenogenesis. Asexual reproduction of this sort is not common, however, as most attempts by worker females to do so are thwarted by either other workers or the queen, who simply consume the eggs upon discovery.

Thus, the altruistic behavior of eusociality, which previously appeared to hold more costs than benefits, could now be seen potentially beneficial in terms of reproductive fitness due to the action of this principle, which has been termed *Hamilton’s rule*. However, his theory of inclusive fitness does not apply only to the Hymenoptera. The logic of Hamilton’s Rule is generalizable to

any situation in which the relative coefficients of relatedness support the *inclusive* fitness benefits outweighing the costs. Quantitatively, this inequality can be expressed as follows:

$$rB > C$$

As discussed above,  $r$  represents the coefficient of relatedness between two individuals,  $B$  is the cumulative representation of benefits resulting from altruism, and  $C$  is the cumulative representation of costs resulting from altruism.  $B$  and  $C$  are considered in the context of reproductive fitness.

J.B.S Haldane is known for the quip that he would “lay down his life for eight cousins or two brothers.” This provided an early description of the later-named process of *kin selection*. This mechanism provides individuals with the ability to succeed reproductively by investing bioenergetic and material resources in the propagation of those genes they share with others, rather than solely in those that they share with their own offspring. Hamilton (1964) equated this notion of Haldane with his inclusive fitness theory. Twenty years later, it was used by Brandon and Burian (1984) in an attempt to better articulate the opposition between supporters of individual and group selection. Since both kin selection and inclusive fitness theory involve the directing of altruism towards whoever shares the most genes with a given individual, Hamilton (1964) considered them to be identical and did not attempt to draw any theoretical distinctions between the two. To simplify this concept, both ideas were taken to be grounded in the notion that recent genetic descent from a common family member provided the shared genes.

## A Continuing Conundrum

Though that story began answering key questions about the Hymenoptera, it was far from conclusive. One main issue is the fact that approximately 136,000 Hymenopteran species are solitary, not eusocial, yet continue to reproduce by means of haplodiploidy.

Additionally, Hymenoptera is not the only order where eusocial insects are found. In fact,

three other orders contain eusocial species: the *Isoptera* (containing all eusocial termites), the *Homoptera* (with some eusocial aphids), and the *Thysanoptera* (with some eusocial thrips). Yet, only the Thysanoptera are haplodiploid like the Hymenoptera. Some Homopteran species are eusocial, but all are diplodiploid like humans. And all Isopteran termite species are both eusocial and diplodiploid.

Despite their not being haplodiploid, many have still attempted to place termite eusociality within the purview of inclusive fitness theory and kin selection, contending that “If relatedness between helpers and reproductives produced averages of 50%, as is the case in monogamous families, only slight ecological benefits are required to favor helping alleles” (Howard et al. 2013, p. 1). In this theory, it is understood that the surrounding ecology can alter fitness tradeoffs enough for the promotion of altruism without large differences in relatedness, like those of the Hymenoptera, ever being necessary. Despite these observations, other researchers have continued searching termites for analogous cases of haplodiploidy. Lacy (1980) hypothesized that the translocation complexes of sex-linked chromosomes should generate higher intrasex coefficients of relatedness than intersex. Others predicted that some form of extensive inbreeding would be the culprit. And finally, some researchers even argued that inbreeding-outbreeding cycles, occurring both intra- and intercolonially, would yield greater intragenerational relatedness than intergenerational, bolstering  $r$  to levels like those of some Hymenoptera. All of these hypotheses would eventually be put to the test with multilocus DNA fingerprinting (Husseneder et al. 1998, 1999), with none proving conclusive. Instead, Husseneder and colleagues concluded that “ecological factors and constraints must be considered a major selective force.”

In summary, these findings demonstrate that standard parent-offspring and full sibling-sibling diplodiploid relatedness of 0.5 (or one even lower) can still lead to the development of eusociality, as long as the local ecology ends up favoring more selective benefits than costs.

Thus, the extreme case of a sister’s relatedness outnumbering that of a daughter by a full quarter is

not required for eusocial behavior. Incidentally, Hamilton's rule always expressed this principle quantitatively; however, solid empirical proof at the molecular-genetic level was absent until Husseneder and others' analyses. In the Hymenoptera, we can see how their haplodiploidy-induced coefficients of relatedness could facilitate the evolution of eusociality, without being either necessary or sufficient. Such an outcome can occur from a multitude of permutations of contributing factors, as long as they result in fitness benefits.

## The Evolutionary Natural History of Eusociality

This theory finds itself further supported by evidence from the natural history of some primitively social wasps. The traditional haplodiploid story of bonds formed intergenerationally among mother and daughter in newly founded colonies was determined, by West Eberhard (1967), not to apply very well to the least evolutionarily developed societies of wasps. Instead, these colonies formed intragenerational *foundress associations* among networks of females who varied in genetic relatedness to one another but were all fully fertile. The many challenges faced by such associations among group members, especially for the most urgent cooperative activities (such as nest defense and raising offspring), result in the pressures of kin selection being extended all the way to "quite distant relatives" (West Eberhard 1975, p. 1). In the further evolved societies of eusocial wasps, along with comparably advanced eusocial ant and bee societies, the *monogynous* process of "worker" females becoming full-time "nest attendants" for the singular foundress queen becomes quite uniform. However, this likely did not occur *ancestrally* in their early evolutionary history and is instead *derived* subsequently, in the case of the social wasps.

Such findings are not intended to imply that imbalances of genetic relatedness are wholly irrelevant to eusociality, rather that they are one of several variables working in concert as it evolves (e.g., Bourke 2014; Kapheim et al. 2015; Waibel et al. 2011). Additionally, one must not ignore Tinbergen's (1963) *Four Questions* and the key

role of *phylogeny* in this narrative. Along these lines, Evans and West Eberhard (1970) provided the following evolutionary history when discussing the evolution of sociality in wasps:

A brief summary of the apparent major steps in the evolution of nesting behavior of solitary wasps may assist in an understanding of the origin of sociality. These steps are progressive in the sense that they must occur in approximately this order and that they lead from simple to more complex behavior. They may be thought of as "rungs in the social ladder" in the sense that the social wasps must once have "climbed" them (Fig. 75); but of course each rung must have its own adaptive value, since many wasps inhabit each rung successfully and the evolution of sociality was by no means preordained. (pp. 114–115)

This inquiry was continued exhaustively, with several subtypes nested within seven overarching steps of social wasp evolution from solitary origins. The resultant list of Hymenopteran milestones on the road to eusociality concludes their findings:

We considered four developments to be preadaptations to sociality: (a) the possession of a nest to which the female returns repeatedly; (b) placement of numerous cells at one site; (c) provisioning more than one cell at a time; and (d) increased longevity of females. All of these would contribute to the likelihood of nesting in groups and, in particular, in groups of close relatives. . . (p. 203)

Herein we find a more thorough explanation for the Hymenopteran universal of haplodiploidy, but relative rarity of eusociality. Those species which are today eusocial succeeded in climbing this social ladder, resulting in the adaptation of behaviors embodying such sociality. This now makes haplodiploidy just one factor among many aiding in the evolution of eusociality. It is not a requirement for such evolution to take place, nor is it a sufficient cause alone when present. Further, and surprisingly for some, Wilson and Holldobler (2005) revealed that the correlation between haplodiploidy and eusociality across species is not even statistically significant.

## The Comparative Method

To get a better picture of the many contributing factors that might be involved, we may step back

and productively apply the *comparative method* to determine which of many permutations of these putatively causal influences might yield eusociality in other taxa. Looking beyond the Hymenoptera, we see that the eusocial termites also possess preadaptations of sociality. One common example takes place when they periodically moult out of their exoskeletons, along with their internal gut lining. Lost with the gut lining are the symbiotic gut protozoa, which allow termites to digest wood and are thus required for survival. To replenish these essential microbiota, the recently moulted termite must consume the anal secretions of nearby conspecifics. This process tilts termites in the direction of increased sociability, which likely contributes to their many other expressions of social behavior, like the construction and defense of nests, protection of offspring, and gathering of vital nutrients. A distinction between wasps and termites, however, is the complete lack of solitary species of termite. Eusociality appears to be universal in that order. Thus, our phylogeny above cannot be as illustrative in explaining their case.

Further complicating matters is the story of the eusocial aphids (Homoptera). They are typically found producing and inhabiting *galls*, insect-induced tumors that spread on their plant hosts. Female aphids are produced parthenogenetically, and a subsection of species have even developed sterile “soldiers” who will reliably sacrifice themselves in battle against any parasites and predators. Inside of these clonal aphid colonies, we find a coefficient of relatedness of 1.0, greater than those full sisters of the Hymenoptera. Presumably, this would lead them to develop even stronger altruistic tendencies through kin selection. However, many aphid colonies have been found with equal relatedness and *without* any signs of eusociality. The preadaptive variables relevant to aphid eusociality are still to be discovered (Abbot 2009).

Lastly, comparable to these aphids, the galls of some thrip (Thysanoptera) species are known to have evolved self-sacrificial “soldier” castes, but the thrips are haplodiploid, and instead of approaching the aphids’ complete clonality, mirror the Hymenoptera with their variable coefficients of relatedness. And similar again to the

Hymenoptera, all Thysanoptera are haplodiploid, while these thrips have only evolved a select number of eusocial species (Gadagkar 1993). Due to greater inbreeding coefficients, the original eusocial thrips are found to possess higher intragroup relatedness, fitting better within kin-selected explanations of altruism (Chapman et al. 2000). Similar hypotheses were levied for the eusocial termites but still lack empirical grounding.

## Multilevel Selection

These examples assist in bringing us back to the dilemma of kin selection versus group selection in explaining insect eusociality. As it now can be shown, neither need be selected over the other. The battle, which some still fight today, was created by early supporters of kin selection (Bahar 2017). These theoreticians viewed group selection as distinct, and occasionally, as completely false. Meanwhile, some group selectionists looked upon kin selection as a subtype of their broader theory, bolstered in its descriptive capacity by relatedness. And though some group selectionists spoke positively upon kin selection, the sentiment was not returned. This is further stated by D.S. Wilson as follows (<https://evolution-institute.org/blog/the-tide-of-opinion-on-group-selection-has-turned/>):

An important development in the history of thinking on kin and group selection is called equivalence – the possibility that the two theories do not invoke different causal processes and are inter-translatable, thereby deserving to co-exist rather than one replacing the other.

Even W.D. Hamilton altered his original stance. This was documented by Sober and Wilson (1998), who discussed Hamilton’s autobiographical essays, where conversations with George Price are shown to have catalyzed the shift. Price, a chemist turned evolutionary biologist, created the famous *Price Equation*, which took Hamilton’s kin selection and mathematically placed it within the theoretical purview of multilevel selection. Instead of adding formulae on relatedness between two individuals, Price

quantitatively addressed the relations between intra- and intergroup gene frequencies.

In so doing, Price (1970, 1972) placed both multilevel selection theory and inclusive fitness theory under one quantitative umbrella, greatly eliminating theoretical distinctions which had previously seemed irreconcilable mathematically (e.g., Frank 1995; Gardner et al. 2011; Hamilton 1975; Korb and Heinze 2004; Kramer and Muenier 2016; Leigh 2010; Lion et al. 2011; Marshall 2011). With this, the *Price Equation* yields the first-ever mathematical model of multilevel selection, through combination of the factors underlying both intra- and intergroup covariance. Wilson and Wilson (2007) have described its impact:

Hamilton's key insight about the importance of genetic relatedness remained valid, but his previous interpretation of inclusive fitness theory as an alternative to group selection was wrong, as he freely acknowledged. (p. 335)

The conversation between Hamilton and Price resulted in this paper: *Innate Social Aptitudes in Man: An Approach from Evolutionary Genetics* (1975). Sober and Wilson (1998, p. 75) summarized it by writing that "...Hamilton re-described inclusive fitness theory as representing a multilevel selection process." The authors believe that Hamilton moved closer than ever before to agreement with Darwin, commenting more extensively that:

Hamilton now saw the multi-group nature of social interactions, regardless of when and where breeding occurs. Social interactions among genetic relatives correspond to the nonrandom formation of groups. The significance of relatedness for the evolution of altruism is that it increases genetic variation among groups, thereby increasing the importance of group selection. Furthermore, any process that increases variation among groups will accomplish the same job... Genetic relatedness loses its status as the exclusive factor responsible for the evolution of altruism and becomes one of many factors that can promote group selection. Hamilton (1975) left no doubt that the difference between inclusive fitness theory and group selection theory is a matter of perspective, not process. Earlier (1963) he had said that group selection should be treated with reserve so long as it remains unsupported by theoretical models. Now those models were available and the major so-called competing theory had vanished. The only process to explain the evolution of altruism was the one that Darwin identified long ago. (pp. 76–77)

Both Price's late-career discovery in a new field and Hamilton's agreeable compliance with its implications for his theory are inherently uncommon, and commented on as such in Price's biography, written by Frank (1995). Instead of defending his views to the grave, Hamilton appeared to be quite pleased with the *post-Price synthesis* of inclusive fitness theory. However, as noted by Sober and Wilson, the rest of his field did not behave so openly. Hamilton's later publications received far fewer citations and general approval from those who had previously embraced him. Most, instead of supporting Hamilton, chose to hold course and maintain a segregated view of kin and group selection. Hamilton (1996) discussed this reception, noting that his 1975 paper was not only cited infrequently but also found itself prone to mischaracterization when cited. Dawkins, for example, cited Hamilton's work in order to claim victory over group selection. The thought of Hamilton remaining fixed in his pre-1975 state seemed bizarre to Sober and Wilson, who marvel at the selective treatment of his work after connection with Price's.

In his 1975 work, Hamilton carefully articulated the separation between kin selection and inclusive fitness theory as being predicated on whether or not recent common descent explained the spread of genes within a group. He went on to demonstrate that this notion of transferring genes through recent common descent was solely used to clarify his quantitative model, not to hold fixed status as a required theoretical facet in understanding altruistic and eusocial evolution. The difference between the two theories was therefore based on this simplification. Kin selection theory held the clarification to be true and necessary, since relatedness among kin was a required part of the term, and inclusive fitness theory was said to be operable without proof of sharing genes through recent common descent.

## The Controversy

Regardless of all this theoretical progress, Dawkins (1976) and others of his same persuasion

continued writing on the belief that sharing genes through recent common descent was required for the evolution of altruistic behavior by kin selection. Others, however, found different solutions to this theoretical problem. With his *genetic similarity theory*, Rushton (1989) claimed that individuals could reliably perceive genetic variance, whether directly related or not, as well as whether consciously or not. This, in his view, forms the basis of human relationships and enduring partnerships. Genetic similarity theory differs here from kin selection in its lack of requirement for shared genes wherever sociality and altruistic behaviors are expressed. Thus, genetic similarity theory diverges from kin selection at the very assumption as does Hamilton's (1975) inclusive fitness theory. In fact, the two theories appear nearly identical when viewed alongside each other. Nevertheless, Dawkins and others failed to acknowledge the potential validity of either, levying the same critique based on an insistence upon the simplifying assumption of shared common descent.

Today, an increasing number of *neo-group selectionists* (Okasha 2006) have written on the theoretical and quantitative accuracy of group selection. With Wilson and Sober's determination that group selection reaches grounds for both plausibility and strong explanatory power (Okasha 2006, p. 177 *et seq.*), kin selection now finds itself again placed within the broader group selection. As Nowak et al. (2010) claim, it is kin selection, not group selection, which "requires stringent assumptions, which are unlikely to be fulfilled by any given empirical system." Found here is the exclusion of processes requiring synergism or the interaction between more than two individuals, as it is assumed that such behaviors are additive and pairwise. Additionally, inclusive fitness theory can only be applied to a limited range of population types (Bahar 2017, p. 277). This places Nowak, Tarnita, and Wilson in solidarity with one another, observing that inclusive fitness theory describes nothing that is unexplainable by group selection.

When observing cooperative group behavior and underlying structure, these present neo-group selectionists place more weight on

ecological variables than relatedness. This is primarily so because of the findings on eusocial insects. In one striking case, researchers both discovered natural super-colonies of unrelated termites and successfully caused the creation of artificial super-colonies in a lab environment by experimentally placing ecological pressures on colonies of genetically unrelated termites (Howard et al. 2013). Combined with the literature above, we continue to find that eusociality and relatedness correlate weakly.

Whereas high levels of relatedness had always been seen as contributory to eusociality, with contention on whether or not it was invariably required, Nowak and colleagues posited that *ecology* should instead hold primacy of causal position. Yet, most still see genetic relatedness as a catalyst for eusociality. Though Hamilton and Wilson agree on its necessity, Wilson has more consistently modeled-in potential nongenetic ecological factors, implicitly lowering his weighting of relatedness. With these distinctions drawn, we are now able to describe, far more lucidly, the true impact of relatedness on cooperative structures where several potential drivers coexist. Relatedness remains necessary, but now within a wider contextual footprint so that its proportion and connection with other variables can take theoretical precedence over its previously perceived supremacy.

Moving to other areas of the solely theoretical literature, we find that intra- and intergroup relatedness receives varied perception. In certain mathematical circles, higher population *viscosity*, born out of the gradual displacement of social group members from their birthplace (also known as *philopatry*), seems to encourage a greater likelihood of cooperative exchange in genetic relatives. However, the core principle driving such altruism appears to simultaneously encourage greater competitiveness among those very same relatives. And in the net, both cooperation and competition cancel, yielding a nearly equilibrated state (Mitteldorf and Wilson 2000; Taylor 1992; Wilson et al. 1992). Yet, other mathematicians (Schonmann et al. 2013) attempted to model comparable scenarios and found the opposite to be true, stating that:

We conclude that contingent forms of strong altruism that benefits equally all group members, regardless of kinship and without greenbeard effects, can spread when rare under realistic group sizes and levels of migration, due to the assortment of genes resulting only from population viscosity. (p. 1)

When actually observing the social insects, as opposed to modeling them mathematically, we find less extreme variation in conclusions. For instance, in the case of the primitive social wasps, far less of today's literature is occupied by models like those of Hamilton's (1964) kin selection theory, with haplodiploidy-inflated coefficients of relatedness stemming from the shared genes of recent common descent. This alteration is primarily due to the documented existence of *foundress associations*, which find fully fertile females cooperating in nest construction and other crucial tasks. Hamilton's theory was seemingly developed in ignorance of these associations, instead operating under the assumption that colonies were created by mother-daughter bonds. The foundress associations have been studied using molecular genetic methods, and though results have not uncovered a full genealogical progression, they were shown to conform qualitatively but not quantitatively to Hamilton's previously determined levels of relatedness requisite for the evolution of kin-selected altruism, in that foundress associations do express higher intragroup than intergroup genetic relation, when genetically contrasted with the broader outside wasp population (e.g., Bluher 2018; Wehren et al. 2007). This appears to be at least partially mediated by behavior, since foundresses have been recorded migrating between nests, presumably optimizing inclusive fitness: "A clear motivation for moving to new nests was high genetic relatedness; by the end of the foundress period all females were on nests with full sisters" (Seppa et al. 2012, p. 1). Researchers have also claimed that relatedness could influence the overall differential dominance seen with nestmates (e.g., Bolton et al. 2006; Sumner et al. 2002). These instances are assumed to begin the evolutionary progression towards eusociality, including towards the evolution of the so-called *sterile* "workers."

## Conclusions

We now come full circle back to the case of the eusocial Hymenoptera. Genetic relatedness is herein established as relevant but not required for the evolution of eusociality in Hymenoptera and beyond. We further realize that *kin selection theory*, as extended in *genetic similarity theory* (Rushton 1989), can be viewed together within Hamilton's most recent version of *inclusive fitness theory* (1975), which (as far as we know) was its final form. Altruism among kin may hence evolve regardless of the degree of relatedness between each relative, given suitable ecological conditions. Nevertheless, in the case of many Hymenopteran species, increasingly shared genetic variance within a group can result in the promotion of gregariousness, and eventually, lead to eusociality.

We therefore conclude that the evolution of Hymenopteran eusociality is best seen through the lens of multilevel selection theory (see Hertler et al. 2020), in which multiple causal influences are recognized to be at work, and that the primacy previously ascribed to haplodiploidy, although highly influential in the history of evolutionary science, was ultimately a very incomplete account of a much more complex phenomenon.

## Hyoid Bone, The

Maura Collins

Department of Speech-Language-Hearing  
Sciences, Hofstra University, Hempstead, NY,  
USA

### Synonyms

Lingual bone; Tongue bone

### Definition

Unpaired, irregular, horseshoe-shaped bone that forms the attachment for the tongue suspends the larynx and assists in respiration, swallowing, and posture.

### Introduction

The hyoid bone is an irregular bone due to its unique quality of not articulating with any bones, rather connecting to other adjacent bones

via muscles and tendons. It forms the attachment for the tongue and suspends the larynx, although not considered to be a part of the larynx itself. This unpaired bone provides attachment for numerous muscles, which function to either elevate or depress the hyoid bone, as well as assist the body in swallowing. In addition, these muscles also help to support the hyoid itself, so that it is able to maintain its position. However, its exact position differs due to individual differences and situational circumstances within these individuals (Gray and Carter 2013; Ferrand 2013; Seikel et al. 2005).

### Anatomical Location and Structure

The hyoid bone is found superior to the larynx, inferior to the mandible, and anterior to the upper cervical vertebrae. The specific level of cervical vertebrae (i.e., C1–7) in which it is anterior to is contingent upon the individual's age and changes throughout the lifespan. It is located at the level of C2 or C3 from birth to age two and then moves slightly from the lower half of C3 and the upper half of C4 in older children and adults. From a sagittal viewpoint, the distance between the hyoid and cervical vertebrae remains the same until around puberty, when the hyoid moves slightly anteriorly (Hudgins et al. 1997). Figure 1 below depicts the position of the hyoid bone in relation to the larynx and mandible.

The hyoid is open posteriorly, thus giving it a horseshoe-like shape. It is comprised of three major components: the body, pair of greater cornu, and pair of lesser cornu. The body, also called the corpus, is convex anteriorly and concave posteriorly. It is also the point of origin or insertion for several muscles. These three components can be found in Fig. 2.

The greater cornu, or horn, articulates with the body laterally and extends itself posteriorly toward the cervical vertebrae. The hyoglossus, a muscle of the tongue, attaches to its outer surface, and the thyrohyoid, an infrahyoid muscle (i.e., below the level of the hyoid), attaches to its lower border.

The lesser cornu, or horn, is a small, cone-shaped projection that sits on the junction of the greater cornu and body. The stylohyoid, a suprahyoid muscle, is attached to its apex (Gray and Carter 2013). Figure 2 below depicts the point of attachment for these muscles.

## Function

The hyoid functions as the necessary attachment of the muscles responsible for respiration, swallowing, and preventing regurgitation. Apart from this role as of anchoring muscles, the hyoid itself is responsible for balancing the head by moving synchronously along with it. That is, if the head moves posteriorly or anteriorly, the hyoid will move posteriorly or anteriorly, respectively. Additionally, when the head moves dorsally, the hyoid

bone rises, and when the head moves ventrally, the hyoid bone lowers (Bibby and Preston 1981).

## Muscle Articulations

There are several muscles anchored by the hyoid that serve several respective functions. These muscles can be divided into two general groups: suprahyoid (i.e., above the level of the hyoid) and infrahyoid (i.e., below the level of the hyoid). The suprahyoid and infrahyoid muscles can be identified in Fig. 3.

The suprahyoid muscles consist of the digastric, stylohyoid, mylohyoid, and geniohyoid. Their primary function is to raise the hyoid bone and larynx. These muscles also play an intricate role in swallowing by helping to raise the tongue and depress the mandible during this process. Swallowing consists of two major parts. The first part is comprised of the food being shifted from the mouth into the pharynx, via the hyoid bone and tongue moving superiorly and anteriorly. This is made possible by the digastric, mylohyoid, and geniohyoid muscles. The second part is comprised of the food passing through the pharynx and the hyoid bone rising back to its original position. The digastric and stylohyoid complete the process of this elevation of the hyoid bone. In addition, these muscles also prevent food from coming back up into the mouth.

The infrahyoid muscles consist of the sternohyoid, thyrohyoid, and omohyoid. Their primary function is to depress the larynx and

**Hyoid Bone, The, Fig. 3** Suprahyoid and infrahyoid musculature (Gray and Carter 2013)

hyoid bone after they have been drawn up in the process of swallowing. Furthermore, the omohyoid is specifically useful for drawn-out inhales.

In addition to the suprahyoid and infrahyoid muscles, the muscles of the tongue also have attachments to the hyoid bone. These muscles consist of the geniohyoglossus, hyoglossus, chondroglossus, and styloglossus. The hyoid provides support for the tongue and attachment for these muscles (Gray and Carter 2013; Seikel et al. 2005).

## Ossification

The hyoid undergoes a lengthy process of ossification (i.e., the process by which a cartilaginous structure becomes hard bone). While it eventually becomes fully ossified in adults, it appears as soft tissue in pediatrics. Although not considered part of the larynx, the hyoid is identified as the earliest laryngeal calcification. In fact, it is the only laryngeal structure that undergoes ossification before

the age of 20 (Turkmen et al. 2012). When ossified, it consists of a bony matrix, osteoid, and osteoblasts.

The hyoid, in both males and females, becomes ossified over general ages in specific anatomical parts. The greater horns become ossified toward the end of pregnancy, and the body becomes ossified following right after the pregnancy. Furthermore, the lesser horns ossify leading up to and during puberty, with the ends of these horns ossifying by age 30. Thus, the hyoid appears as a single bone by age 30, while appearing as two separate structures, the corpus and posterior cornus, in earlier ages (Turkmen et al. 2012, 2014).

## Abnormalities

Abnormalities in the hyoid bone itself are often found together with cleft lip, cleft palate, or Pierre Robin syndrome (Turkmen et al. 2012, 2014). In addition, abnormalities associated with muscle articulations to the hyoid bone can also cause

pathologies. Ossification of the stylohyoid ligament, part of the stylohyoid muscle apparatus, causes Eagle's syndrome. This is marked by chronic throat pain and is due to tissue structures applying excess pressure to the stylohyoid (Baig et al. 2012). Additionally, abnormal positioning of the hyoid can lead to obstructive sleep apnea (OSA). OSA is due to a blockage of the pharynx by the tongue during sleep and leads to snoring or insufficient inhalation of oxygen (Gent et al. 2014).

## Fracturing

The hyoid is rarely fractured naturally or as a result of sport injury, due to its location inferior to the mandible, which conveniently provides the hyoid protection. However, if the hyoid is fractured, it is generally a result of strangulation. A fractured hyoid leads to great pain in speaking and swallowing, due to the tongue having several muscle attachments at the hyoid.

## Hypothalamus

Shivani Peters  
Hicksville, NY, USA

## Definition

A structure of the brain responsible for maintaining a stable internal environment in the body.

## Introduction

The hypothalamus is located in the brain underneath the thalamus and above the pituitary gland. It is responsible for maintaining stable internal conditions, known as homeostasis, in the body. The hypothalamus, which is part of the limbic system, receives sensory information from the environment and either sends signals to the autonomic nervous system or releases hormones to the endocrine system in order to correct bodily imbalances. Hypothalamic hormones interact with the endocrine system via the pituitary gland by controlling the production of pituitary hormones. Some processes regulated by the hypothalamus are heart rate, blood pressure, body temperature, thirst, water excretion, childbirth, sleep, hunger, sex drive, rage, and fear (Beaton 2013).

## Interaction with the Autonomic Nervous System

The autonomic nervous system, which is split into the sympathetic and parasympathetic pathways, works with the hypothalamus to regulate autonomic functions and reflexes. Neurons in the hypothalamus are connected to various receptors in the body and receive a wide array of environmental and internal sensory signals such as pain, change in blood levels, and changes in light, temperature, and smell. After receiving these signals, the hypothalamus makes direct and indirect connections with sympathetic and parasympathetic neurons in the brain stem and spinal cord which cause the body to react and return to homeostasis. The hypothalamus, via the autonomic nervous system, is in control of processes such as blood pressure, heart rate, breathing, digestion, sweating, salivation, and bladder emptying (Beaton 2013; Dampney 2011; Hall and Guyton 2006).

## Interaction with the Endocrine System

The hypothalamus is linked with the endocrine system by the interaction its hormones have

with the anterior and posterior pituitary glands. Hormones produced by the hypothalamus are:

- **Thyrotropin-releasing hormone (TRH)** – triggers the release of thyroid-stimulating hormone (TSH) and prolactin which in turn regulate metabolism, brain development, muscular control, and energy.
- **Gonadotropin-releasing hormone (GnRH)** – triggers the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) that are connected to puberty and reproductive function.
- **Growth hormone-releasing hormone (GHRH)** – triggers the release of growth hormone (GH) that controls physical development in children and metabolism in adults.
- **Corticotropin-releasing hormone (CRH)** – triggers the release of corticosteroids that help regulate physical and emotional stress, metabolism, and immune response.
- **Dopamine (DA)** – when acting as a hormone and not a neurotransmitter, DA inhibits the release of prolactin which, in turn, stops the production of milk.
- **Somatostatin (SS)** – inhibits the release of growth hormone (GH) and thyroid-stimulating hormone (TSH).
- **Oxytocin (OXY)** – stimulates uterine contraction during childbirth and the lactation reflex during breastfeeding.
- **Vasopressin/antidiuretic hormone (ADH)** – increases water absorption in the kidneys and constricts blood vessels.

After hormones are produced in the hypothalamus, they are transported to either the anterior pituitary or the posterior pituitary. Oxytocin and vasopressin are released into the bloodstream via the posterior pituitary and act on distant target organs. TRH, GnRH, GHRH, CRH, dopamine, and somatostatin all travel to the anterior pituitary where they control the release of pituitary hormones (Beaton 2013; Hall and Guyton 2006; Jones 2010).

## Behavioral Functions

Stimulation or lesioning of the hypothalamus can have extreme emotional and behavioral effects on animals and humans alike. Some emotional reactions caused by stimulation are fear and punishment behaviors as well as changes in sexual drive. Stimulation of the lateral hypothalamus causes extreme thirst, increases in feeding and energy, as well as rage and fighting behavior (Berthoud and Münzberg 2011). Lesioning that same area causes an opposite reaction in the form of a decrease in drinking and eating to a point of starvation, as well as extreme passiveness. Stimulation of the ventromedial nucleus of the hypothalamus causes effects such as satiety and peaceful behaviors. Lesioning that same area has the effect of increases in eating and drinking as well as extreme rage (Hall and Guyton 2006).

## Introduction

Hyracoidea are an order with only one extant family, Procaviidae. Though the Procaviidae family mostly resemble medium-sized rodents, around 2–3 kg in size, they are more closely related to elephant and sengi and sit in the super-order Afrotherian. Five species now form this family that can be found throughout Africa and the Middle East; the rock hyrax (*Procavia capensis*, Fig. 1), yellow-spotted rock hyrax or bush hyrax (*Heterohyrax brucei*), western tree hyrax (*Dendrohyrax dorsalis*), southern tree hyrax (*Dendrohyrax arboreus*), and the eastern tree hyrax (*Dendrohyrax validus*). All species, with the exception of the eastern tree hyrax which is threatened across its range, are currently relatively common across their wide-ranging distribution.

Rock hyrax, the most studied of all hyraxes, live in arid savanna, rocky outcrops across sub-Saharan Africa, and the North-East Africa through to the Middle East. Some populations

**Hyracoidea, Fig. 1** Rock hyrax (*Procavia capensis*) at RZSS Edinburgh Zoo. (Photo by Declan Duffy)

have also moved into urban areas taking advantage of man-made holes and crevices (McPherson et al. 2016).

Bush hyrax can be found across the east of Africa with an isolated population in Angola, living, often in close association with rock hyrax, around rocky outcrops and boulders that are surrounded by bush or woodland (Barry and Shoshani 2000).

Dendrohyrax research had been limited to captive studies in the late 1970s and 1980s but with technological advances there has been an increase in wild studies on these species. Southern Tree hyrax are found from East Africa to South Africa and as with all tree hyrax they are arboreal, spending most of their time high in the canopy or in tree holes making them difficult to observe (Milner and Harris 1999a). Eastern tree hyrax distribution is severely fragmented across Tanzania and into south eastern Kenya (Roberts et al. 2013). High population densities were recorded in undisturbed forests and canopy structure (important for arboreal pathways) and is deemed to be a limiting feature of eastern tree hyrax populations (Topp-Jørgensen et al. 2008).

Other than being a food source for humans (Fa et al. 2000), very little has been published about the western tree hyrax. They are found in the western area of Africa from Sierra Leon to western Uganda (Shultz and Roberts 2013). Prey for leopards, raptors, pythons, golden cats, servals, chimpanzees, and bush meat for humans, they have also been noted in instances of play by chimpanzees in Bossou, Guinea (Hirata et al.

2001). This chapter summarizes what is known so far of the hyrax behavior and cognition.

## Nutrition and Feeding Behavior

All hyrax are hind gut fermenters, a category that also includes the lagomorphs, rodents, and callitrichid primates. They have an unusual two chamber stomach with a glandular and non-glandular section. They have a very well-developed and efficient digestive system with fermentation taking place in the caecum of the large intestine. A long transit time allows microbial fermentation to aid digestion and these microbes produce volatile fatty acids which are likely to serve as an energy source for the hyrax (Leon 1980). All hyrax defecate in a single spot, often communally, known as a midden or latrine.

Rock hyrax are grazers, feeding mainly on grasses in the wet season but moving to browse later in the dry season (Hoeck 1975). Species from the Dendrohyrax and Heterohyrax genus are considered to be more browsers than their grazing cousins. Tree and shrub leaves make up the bulk of bush hyrax diet though they will also consume tree bark as well as flowers, fruits, and grass, particularly in the wet season (Hoeck 1975 and Girmay et al. 2016).

All dietary information on the tree hyrax has been taken from studies on the southern tree hyrax species. Southern tree hyrax predominately consumes tree leaves but also shrubs, flowering plants,

and ground forbs (Gaylard and Kerley 1997; Milner and Harris 1999b).

Hyrax dentition reflects the diet with the grazing rock hyrax possessing hypsodont molars (high crowned teeth that are good for fibrous food) and the other species having brachydont molars (low crowned/short teeth). The length of the upper premolar series also varies; in bush hyrax they are equal to the length of molar series. Rock hyrax have much shorter upper premolars than molars, and in the genus *Dendrohyrax*, the upper premolars are longer than molars (Jones 1978). They possess well-developed upper incisors shaped into sharp tusks and lower incisors that are unsuitable for biting but used for grooming fur. The molars are used for biting and chewing food quickly, allowing the ability to ingest food quickly (Sale 1966). The rock hyrax basal metabolic rate is low and as such they have low energy requirements (Leon 1980). Milner and Harris (1999b) found that southern tree hyrax also show behaviors typical of the low metabolism strategy shared with the rock hyrax. Other arboreal folivores, such as arboreal marsupials and sloths, also share this strategy, driven by a diet with low nutritional value. However, short feeding bouts from quick consumption and low intake combined with low activity levels has benefits, through better predator avoidance strategies (Sale 1966).

## Behavior

### Sociality

Rock hyrax and bush hyrax are gregarious, diurnal species, both forming similar social structures. Their grouping consisting of a harem with one dominant male and females with their offspring (Fourie and Perrin 1987). Group sizes are usually between 10 and 20 individuals, though bush hyrax group sizes have been recorded as large as 34 individuals (Barry and Shoshani 2000) and there have been reports of rock hyrax group sizes reaching up to 80 individuals (Olds and Shoshani 1982). They forage socially, individuals often forming sentries and can also form heterospecific groups (Hoeck 1975).

Grooming has been recorded in most hyrax species. The lower incisors are rubbed through the fur, a behavior which has been observed socially in captivity with the bush hyrax and western tree hyrax (Jones 1978). All hyrax also possess a long nail on the inner toe of the hind foot, which is used for scratching.

Basking is an important behavior as hyrax have a poor ability to thermoregulate. The two social species' will also huddle in groups for warmth and tree hyrax can insulate against cooler nights in tree hollows. Indeed, whilst studying the southern tree hyrax, Milner and Harris (1999b) recorded lower activity levels when the ambient temperature was cooler.

Tree hyraxes are solitary, nocturnal, and arboreal animals, though the extent of these characteristics varies geographically. They are active at night but captive studies found that they will feed during the day (Rudnai 1984). Milner and Harris (1999b) observed feeding at dusk and dawn and regular diurnal movement as well.

Predators strongly shape the behavior and activity patterns of all hyrax populations (Druce et al. 2006). Out from under the safety of cover, the hyrax are more susceptible to predation and so large group sizes and sentinels, as well as staying close to refuge sites, are all coping strategies. Where large avian predators are present, their activity pattern shifts to a more nocturnal one (Milner and Harris 1999b). Druce et al. (2006) modelled the foraging behavior of hyrax against other factors and found interactions between season and foraging distance, suggesting that during dry period rock hyrax risk greater chance of predation as they seek food farther from their dens. Equally human disturbance also has an effect, where there is an increase in hunting by snares, the tree hyrax become more arboreal (Topp-Jørgensen et al. 2008).

### Locomotion

Hyrax are quadrupedal plantigrade mammals, but each species in the Procaviidae family have become adapted to their specific niche. Tree hyrax prefer to travel across upper tree zone and several studies have found evidence that they spend a higher amount of time on the ground

than was understood previously (Rovero et al. 2014; Milner and Harris 1999b). Despite footpads with hoof-like nails, they are excellent climbers ascending and descending quickly (Richard 1964). Jones (1978) noted that the feet of the tree hyrax may be rotated inward to aid tree climbing and captive individuals have been observed holding vines in their teeth to help ascend the tree.

Rock hyraxes are also good climbers, and Serruya and Eilam (1996) observed the rock hyrax to climb onto low branches and bask in the sun. They have a special adaptation for squeezing into crevices or small holes where they spend the night, with early morning and evening making up the core activity periods (Olds and Shoshani 1982). They use the presence of whisker like hairs that cover their body to help navigate around their rock crevice surroundings (Sarko et al. 2015). Their locomotion behavior is made up of very rigid and conserved movements reminiscent of stereotypical behavior (Serruya and Eilam 1996). They move in short bursts or chunks and this chunking process is also seen in the learning process as a way of managing an increasing load of information (Serruya and Eilam 1996). This behavioral conservation strategy may require less cognitive effort to allow them to spend more energy on predator vigilance.

As the wet season ends and the dry season begins, male aggression increases in the rock hyrax, who will chase and bite other males and wounds are frequently observed during this period (Serruya and Eilam 1996). Aggressive interactions include snarling and chasing, though rarely does physical contact occur with tree hyrax (Milner and Harris 1999b).

## Reproduction

Sexual maturity is reached around 28 months in males and 16 months in females, with seasonal mating being triggered by the photoperiod (Fourie and Perrin 1987). Males may reach puberty earlier than this (+16 months) but are often prevented from mating by other older males (Sale 1970). There is evidence of precocial puberty being reached by females from 4/5 months old, though this is limited to certain geographical areas

(Fourie and Perrin 1987). Rock hyrax litter size is around three individuals and older or younger individuals tend to produce smaller litter sizes (Fourie and Perrin 1987).

At around 17–24 months, adolescent male rock hyraxes will be forced to disperse from the natal group and find their own group or join a bachelor group on the periphery of the natal group (Sale 1970). Adult male rock hyraxes may only be with a group for around 2 years before being challenged and evicted by a bachelor (Fourie and Perrin 1987).

A clear reproductive season is apparent in the bush hyrax corresponding with the wet season. Bush hyrax population sizes will fluctuate with rainfall (Barry et al. 2015). Thus, reproductive season is likely driven by resource availability and that this corresponds to rainfall in the equator region and photoperiod outside of this zone (Barry et al. 2015). This is particularly apparent in areas that experience two rainy seasons and bush hyrax correspondingly experience two peaks in reproduction (Hoeck 1975). No specific birth period has been noted in some southern tree hyrax populations (Milner and Harris 1999b), but there was a clear calling season, indicating a reproductive season exists.

Hyrax has a particularly long gestation (6–8 months) and growth phase for their size and lifespan (living up to 12 years). Both these features are likely to be residual features from their larger ancestors (Olds and Shoshani 1982).

In addition to the advantage of larger group sizes, the heterospecific groups of rock and bush hyrax also offer the benefit of nursery care for their precocial calves (Barry and Shoshani 2000). Generally, the lactation period is less than 6 months in rock and bush hyrax (Fourie and Perrin 1987; Barry and Shoshani 2000). Infant rock hyrax develops the majority of vocalizations between the ages of 2 and 15 months (Fourie 1977).

## Communication

All five hyrax species are very vocal, with particular vocalizations specific to each species. Rock hyraxes are known to make up to 21 vocalizations (Koren and Geffen 2009). Male and female rock hyraxes produce a loud alarm call but male rock

hyraxes also have a much more complex vocal communication advertising a variety of attributes about the communicator to others; from attracting a mate, display the singers' identity (Koren and Geffen 2011), age, social status, and body mass as well as signaling distress (Koren and Geffen 2009). Only males sing and counter-sing and singers are usually older, more dominant, and have higher cortisol levels (Koren and Geffen 2009). The function of singing is not clear but as the frequency of singing reduces after the mating season, it is likely that this is a form of sexual advertising (Koren and Geffen 2011).

Rock hyrax calls are made up of wails, chucks and snorts. The chucks are emitted in one single breath leading Koren and Geffen (2009) to deduce that this implied the size of the singer as larger lungs are needed for to hold the sound.

In addition to vocal communication, chemical communication in the hyraxes is likely. They possess a distinct vomeronasal system (Olds and Shoshani 1982), and tree hyrax have been observed to scent mark by rubbing their glands on branches, and at least in the western tree hyrax, producing a scent that smells of cinnamon (Richard 1964).

Both male and female southern tree hyrax make deep croaks followed by loud screaming vocalization, which is more prevalent in the end of the dry season (Milner and Harris 1999b). There may be some link between call season and reproduction, despite little evidence of birth seasonality, as only single females will call, though the purpose of the call may be to defend a territory rather than to attract a mate (Milner and Harris 1999b). Western tree hyrax, as with the southern tree hyrax, emit a series of long screams that gradually get louder, culminating in a crescendo and abrupt climax (Shultz and Roberts 2013). This type of ending also seen in other hyrax is considered important for the communication, and in rock hyrax more males respond to songs with climatic endings (Demartsev et al. 2017).

There may be up to 50 species or subspecies in the family Procaviidae which is continuously being disputed. At present, there are at least 24 subspecies of *Heterohyrax brucei* alone (Barry and Shoshani 2000). There is some debate

as to whether the eastern tree hyrax is a separate tree hyrax species or if it is a subspecies of the southern tree hyrax; however, its distinct call characteristics have kept it apart from the southern species at present (Roberts et al. 2013). Current studies are investigating whether different calls can help to shed further light onto hyrax species identity (Koren pers. comm.). One example of a recently suggested new species is the geographically isolated Benin tree hyrax, which has a distinct vocalization from other western tree hyrax (Bearder et al. 2015). Research by Kershenbaum et al. (2012) suggests cultural drift explains the formation of distinct dialects, where hyrax songs diffused over short distances. As no genetic correlation in male vocal song has been found (Koren and Geffen 2011), the ability of song learning in hyrax needs further consideration (Kershenbaum et al. 2012).

## Cognition

Very little has been published on the cognition of Hyracoidea species. However, as suggested by Limacher-Burrell et al. (2016), the extensive social nature of the rock hyraxes and their large vocal range and repertoire indicate that their cognitive make-up is likely to be as complex as in other mammals. Other Afrotherian species show high level cognitive abilities (Plotnik et al. 2010). Depending on the evolution of this cognitive process, hyrax may possess their own cognitive specialties (Limacher-Burrell et al. 2016).

A small number of studies investigating the rock hyrax neuronal systems have been published aiming to enhance the understanding of the evolutionary processes associated with the brain's nuclear organization (Limacher-Burrell et al. 2016; Gravett et al. 2009). Studying the amygdala (an area in the brain, thought to be important in behavioral activities), Limacher-Burrell et al. (2016) found that the hyrax amygdala seems quite conserved, making this good baseline for studying other more specialized mammals.

Gravett et al. (2009) observed two distinct neuronal types in one area of the rock hyrax brain that differ from previous studies of this

area in other mammals. Leading the authors to suggest there may be usual effect on the rapid eye movement (REM) sleep patterns of this species and possibly other species within the Afrotherian superorder. Gravett et al. (2012) analyzed the sleep patterns of wild caught hyrax in a lab setting and found the REM stage of sleep was extremely short, at only around 6 min out of a 15.89-h sleep. Whereby, in other mammals, REM sleep is normally around 17% of total sleep time. A novel type of sleep state was also observed, whereby the brain activity appeared to be in the waking stage and the muscles activity, as seen in the EMG, were reduced in amplitude (similar to slow wave sleep) but not as reduced as REM (Gravett et al. 2012).

## Conclusions

There is a dearth of information on Dendrohyrax species in comparison to the other species, especially the rock hyrax, which has received the most attention. Detailed behavioral studies are needed in these other species, in particular investigating their thermoregulation behavior and reproductive drivers. The unusual neuronal patterns, found in the rock hyrax brain, and their novel sleep states is a noteworthy finding and its existence in other similar taxa would be of further evolutionary interest. Overall, despite the small number of extant species currently recognized in the Hyracoidea there is much more to be understood about these unusual animals. The relatively long gestation and growth period suggests a high level of learning, particularly in terms of vocal communications. Rock hyrax show complex, repeated vocalizations (or songs) that is rarely documented in mammals beyond animals such as cetaceans and primates, considered to have a high cognitive ability. Geographical variations in these songs as well as the function of the song pattern and information transfer have been investigated. Extended exploration of these vocalizations to determine the learning mechanisms, dispersal pathways, and complexity across the Hyracoidea would help to further our understanding in the field of communication.

## IACUC

Nicole Duffee<sup>1</sup> and Melissa Shyan-Norwalt<sup>2</sup>

<sup>1</sup>Education and Scientific Affairs, American Association for Laboratory Animal Science, Memphis, TN, USA

<sup>2</sup>Department of Psychology, University of Cincinnati, Cincinnati, OH, USA

### Introduction

An institutional animal care and use committee (IACUC) is a requirement at most institutions that have animal research or teaching programs in the United States. Similar committees exist at research and teaching institutions in other countries (Varga 2013). These may go by names other than the IACUC, such as animal research ethics committee, but they have similar functions in complying with national or regional mandates. This chapter describes IACUCs in the United States.

An IACUC is charged with self-regulation over animal care and use in compliance with all US federal laws, regulations, policies, and guidelines that govern animal welfare in research, testing, or teaching (National Research Council 2011). Self-regulation allows an institution the flexibility to determine how it will conduct its IACUC procedures in ways that are most efficient and productive for its own research program. Although self-regulating, an IACUC must meet

certain requirements – its members must be appointed to fill specific roles for which they must be qualified, and the committee must carry out its specific responsibilities. The committee is appointed by a chief institutional official, such as a dean of research or a president or vice president. The committee members must include scientists, a member unaffiliated with the institution, and, in some cases, a nonscientist. Unaffiliated members are intended to represent public attitudes about animal research. An attending veterinarian with appropriate qualifications in laboratory animals must be appointed as an ex officio member to consult on veterinary matters in protocol review and other committee activities. Researchers interact with their IACUC in four ways: submission of their animal protocols for review, identification of occupational health and safety issues related to an animal protocol, participation in training mandated by the IACUC, and inspection of their laboratory areas where animals are housed or studied.

### Ethics of Animal Research

In the United States, federal regulations, policies, and guidelines provide the framework for humanely conducting animal research. The Federal Animal Welfare Act (AWA) covers the use of animals in research, teaching, and exhibition, and it is enforced by the Animal Welfare Regulations and Standards (AWR) (United States

Department of Agriculture 2017a). The AWA and AWR first date from 1966. Since then, there have been many amendments to the law and changes in the regulations. Animals covered by the law and regulations are limited to warm-blooded animals with the exclusion of laboratory strains of mice, rats, and birds, as well as agricultural animals that are used for teaching or research in food and fiber production. Therefore, covered animals include nonhuman primates, dogs, cats, rabbits, guinea pigs, hamsters, gerbils, wild species of rats and mice, and so on. Farm animals are covered when used for biomedical research. Cold-blooded species – amphibians, reptiles, fish, and invertebrates – are excluded. Any institution conducting research or teaching with covered species must be registered with the United States Department of Agriculture (USDA) via the Animal Care Program. The registered institution must have an IACUC, see to the training or qualifications of personnel in key areas of animal care and use, conduct semiannual inspections of its program and facilities, maintain required documentation, file annual reports with the USDA, and submit to unannounced inspections. The USDA's Animal Care Policy Manual provides detailed interpretations of the AWR (United States Department of Agriculture 2017b). It specifies compliance with two nonfederal guidelines: The AVMA Guidelines for the Euthanasia of Animals (American Veterinary Medical Association, AVMA) and the Guide for the Care and Use of Agricultural Animals in Research and Teaching (Federated Animal Science Societies, FASS) (American Veterinary Medical Association 2013; Federated Animal Science Societies 2010).

Additional oversight is provided under the Public Health Service Policy for the Humane Care and Use of Laboratory Animals (referred to as the PHS Policy herewith). It is a federal mandate that enforces the US Health Research Extension Act of 1985 (United States Department of Health and Human Services 2015). It covers a larger range of species: all vertebrates. Therefore, many species excluded by the AWA and AWR are covered by the PHS Policy – in particular, laboratory strains of mice, rats, and birds; reptiles; and amphibians and fish as well as their larval forms

posthatching. The PHS Policy requires compliance with the *Guide for the Care and Use of Laboratory Animals* (National Research Council 2011) as well as the AVMA and FASS guidelines mentioned above. Compliance with the PHS Policy is required when an institution's funding source for animal research and teaching is the US Federal Government. An institution must file an Assurance with the Office of Laboratory Animal Welfare (OLAW) at the National Institutes of Health (NIH) (National Institutes of Health Office of Laboratory Animal Welfare 2017a). The assured institution must have an IACUC, see to the training or qualifications of personnel in key areas of animal care and use, maintain required documentation, conduct semiannual inspections of its program and facilities, file annual reports with OLAW, and submit to scheduled inspections. Many research institutions must comply with both the AWA/AWR and the PHS Policy because of the dual conditions of using USDA-covered species and having research supported by federal funding.

Besides those described above, other laws, regulations, and guidelines may apply to animal activities. For example, anesthesia and analgesic medications in the treatment of laboratory animals often involve the use of controlled substances, falling under both state statutes and federal law and regulations. Because of the complexity of the regulatory landscape, researchers need to rely on their institution's compliance staff for ensuring that all relevant mandates are followed in the conduct of their animal studies. Compliance personnel are typically affiliated with the IACUC office, the animal facility, or the environmental and safety office.

Many institutions exceed minimum compliance with regulations governing the use of animals in research by attaining accreditation for excellence in laboratory animal care. Accreditation distinguishes an institution for providing quality in animal welfare and good science in animal research. AAALAC International is a private, nonprofit organization that is the only worldwide accrediting body for animal care and use programs. Accredited institutions undergo an extensive self-evaluation by preparing a Program Description according to a template. The Program Description is used to assess the institution in a

site visit. Institutions maintain accreditation by submitting annual reports and repeating the assessment process every 3 years. AAALAC International is well recognized among scientists, research institutions, grant agencies, and professional associations. Accreditation is a critical factor in funding decisions by some grant agencies and is a requirement by others (e.g., the American Heart Association and the American Stroke Association) (American Heart Association, American Stroke Association 2017). AAALAC accreditation requires compliance with three primary standards: the *Guide for the Care and Use of Laboratory Animals*, the *Guide for the Care and Use of Agricultural Animals in Research and Teaching*, and (in Europe) the European Convention for the Protection of Vertebrate Animals Used for Experimental and Other Scientific Purposes – Council of Europe (ETS 123) (AAALAC International 2017). In addition, other standards may be required if relevant to the accredited program.

Other than those mentioned above, guidelines, codes of ethics, and position statements have been developed by scientific professional or membership organizations to express commitment to ethics in animal research and to support the highest standards in the care and use of animals in research and teaching. For example, the National Research Council's *Guidelines for the Care and Use of Mammals in Neuroscience and Behavioral Research* focus on general animal care and use principles and considerations in this area of research (National Research Council 2003). The American Psychological Association's code of ethics, *Guidelines for Ethical Conduct in the Care and Use of Nonhuman Animals in Research*, exhorts psychology researchers to consider the costs and benefits of procedures involving animals (American Psychological Association 2012). This document lays out principles for research justification, personnel, care and housing of laboratory animals, experimental procedures, field research, and educational use of animals. The American Association for Laboratory Animal Science has position statements on many issues, including *Alleviating Pain and Distress in Laboratory Animals* and *Animal Use in Precollege Education* (American Association for Laboratory Animal

Science 2017). The American College of Laboratory Animal Veterinarians has many position statements, including reproducibility of animal studies; and medical records for animals used in research, testing, and teaching (American College of Laboratory Animal Medicine 2017).

A central theme in the ethics of animal research is the consideration of alternatives to the use of animals in experimental studies and teaching. The AWA and AWR stipulate that principal investigators consider "alternatives to any procedure likely to produce pain to or distress in an experimental animal. . ." (United States Department of Agriculture 2017a). These alternatives are interpreted as the three R's – principles first published by Russell and Burch and known as Replacement, Reduction, and Refinement (Russell and Burch 1992). These principles aim to minimize the use of animals and their pain or distress, while still achieving critical scientific objectives for advances in health and medicine. Replacement means that, where possible, animals should be replaced by nonanimal methods. Reduction means that the number of animals should be reduced to the minimum needed to obtain statistically significant data. Refinement means that methods used with animals should be modified to lessen the potential for pain or distress in those animals that must be used.

To responsibly conduct animal research, investigators must be qualified and therefore trained in areas of: relevant institutional policies, biological requirements of the species they will work with, safe and humane handling and restraint of the animals, humane conduct of animal procedures, and avoidance or alleviation of animal pain and distress. Animal use protocols (see next section) should identify personnel who will perform the animal procedures. These individuals should be verified as suitably trained or they must receive such training before the protocol is approved. For example, to conduct a surgical procedure on animals, researchers must be qualified on the following as applied to animals: aseptic technique; principles of surgery and the particular surgical technique to be used; anesthesia principles and technique for induction, maintenance, monitoring and recovery; and postoperative monitoring and

care. The IACUC must have evidence that these individuals know what clinical signs to look for in a given species so they can recognize pain or distress arising from their procedures. Otherwise, signs of pain in animals may go unrecognized. For example, in mild to moderate pain, dogs may not whine, limp, cringe, or even reduce their food intake. Evidence of pain may be more subtle, such as turning the head toward the painful area, occasional lip licking, licking or sniffing the painful area, or even just a reduction in overall activity level. Researchers must be competent to recognize signs of pain in the species and to administer pain medications and other treatments as specified in their protocols. In addition, the AWA/AWR stipulates that all personnel be trained on the reporting of deficiencies in animal care and treatment by any employee of the facility (United States Department of Agriculture 2017a).

Each institution has a training program to assure that researchers and other personnel learn how to work humanely and safely with the animals. Often these programs combine training modalities. Online courses convey in-depth information on ethics, policies, and species information. Hands-on instruction develops skills in animal procedures. Facility tours orient researchers to important rules and operations. Face-to-face training builds rapport between researchers and facility personnel, and researchers learn whom they can contact for assistance. Although facility staff provides training services for common techniques used in conventional species, specialized techniques or handling of unusual species may be best taught by the researchers themselves. For example, in field studies, personnel may need training in dart-tranquilizing and tracking systems implantation, and experienced researchers may be the best qualified to train on these techniques (Gannon and Sykes 2011). Therefore, IACUCs and investigators should collaborate on how to meet the training requirements for a protocol.

## Animal Use Protocol

Every use of animals, whether for a scientific or an educational purpose, must be reviewed in an

animal use protocol submitted to the IACUC (United States Department of Health and Human Services 2015; United States Department of Agriculture 2017a). No study or instruction with animals can be initiated prior to IACUC approval. Animal use protocols must fully describe a research project to enable the IACUC to adequately review the proposed care and use of the animals, in alignment with legal requirements and institutional policies. Prior to IACUC review, a veterinary consult helps address important elements in the protocol related to animal welfare and minimizing animal pain and distress. Per PHS Policy, a protocol may be approved for a maximum of 3 years. For ongoing studies, a new review is required at least every 3 years.

A protocol must be carefully planned as all study personnel will be expected to adhere to it. The protocol is like a contract for the privilege of using research animals, and its terms must be strictly upheld. Nevertheless, a protocol can be written with flexibility to allow handling of uncertainties, give reasonable options, and avoid overly restrictive parameters. For example, multiple acceptable options for anesthetic and analgesic regimens may be included by referencing a standard operating procedure (SOP) of the institution. This would allow changes in the study's drug regimens according to the current SOP and its future amendments. Incorporating flexibility in the protocol can reduce the chances of noncompliance and avoid administrative delays due to future protocol amendments. Investigators should confer with the attending veterinarian or the IACUC office on how to prepare a protocol with the flexibility needed to accomplish scientific goals.

The USDA requires that investigators consider alternatives to procedures that may cause more than momentary or slight pain or distress to the animals. The USDA also requires that studies are not duplicated unnecessarily. Most often, a literature search is conducted on alternatives to the use of animals related to the three R's principles of replacement, reduction, and refinement. The protocol should describe the search strategies used. If no alternatives can be found, investigators are asked to write a narrative description of the methods and sources used to determine that alternatives were not available.

Animal cognition studies frequently include invasive procedures such as brain surgery, implantation of electronic devices in the brain or body, lesioning practices, chemical manipulations, and other invasive techniques. If animals will undergo painful and/or distressful procedures or conditions, humane endpoint criteria should be included for ending a study prematurely, relieving pain or distress, or euthanizing the animals. Determining the level of pain and discomfort is critical for animal welfare. The description of the experimental design, animal procedures, and humane endpoints should allow the IACUC to understand the care and use of animals from start to finish. Thereby, the IACUC can assess the likelihood of and the intensity of pain or distress the animals may experience in the proposed study. The IACUC considers whether the methodology is appropriate for the intended use of animals and whether less invasive or less painful procedures would be suitable alternatives to the proposed methods.

Although protocol forms vary by institution, they typically cover the same type of information. Animal use is specified by species, age, weight or size, sex, genetic make-up, microbiological status, source, housing location and type, animal identification methods, number of animals to be used, and method of transportation. Study objectives should explain the aim of the study and why the study is important to human or animal health or to the advancement of knowledge or education. A rationale for the use of animals should include justifications for the appropriateness of the species and the number of animals to be used and, if possible, refer to a power analysis for the animal group size. A protocol should answer questions such as the following: Will animals be physically or chemically restrained? If so, how will the animals be monitored while restrained? If the restraint method is physical, how will the animals be adapted to the restraint device? What limits, e.g., duration, will be applied to the restraint? If animals will be trained to cooperate with procedures, how will the training program be conducted? Will animals be submitted to restrictions in food or water? If so, the restrictions must be scientifically justified and limited to acceptable standards to prevent distress. If drugs will be used,

whether for chemical restraint, anesthesia, analgesia, or testing, what will be the dose, frequency and route of administration, and duration of treatment? If a paralytic drug will be used, how will adequate analgesia be assured? How will animal pain or distress be assessed during all the procedures? How will aseptic technique be applied for catheterizations and surgeries? In a surgery, how will the animal be monitored for physiological parameters and for effectiveness of analgesia during the operation? How will the animals be monitored for recovery from anesthesia and surgery? How will these observations during anesthesia and surgical recovery be documented and at what frequency? What care will the animals receive postoperatively or for chronic catheterizations and implants? If biological samples will be collected, what will be the anatomical sites, frequency of collection, and sample volumes? Will anesthesia or sedation be used for sample collection? What adverse events might be anticipated in the animal procedures, and how might these events be managed? How will animals be disposed of at the end of the study – by adoption, transfer to another protocol, or euthanasia? If animals will be euthanized, what methods will be used?

The protocol must be thorough, accurate, and clear. Approval of a study may be delayed if the IACUC needs clarification or additional information. It is important to write in language a nonscientist would understand. Each specialty has its own jargon, and animal cognition and behavior are no exception. Consider that most IACUC reviewers are not experts in all scientific disciplines, so common words should be used. Furthermore, it is possible that a protocol may be read by regulatory and accreditation authorities, if the study is inspected at a future time.

## **Animal Housing and Enrichment**

Housing and living conditions can greatly affect how animals respond as research subjects in behavior and cognition studies, as well as in many other disciplines (Zelevnikow-Johnston et al. 2017). Laboratory animal facilities provide standardized care and a uniform environment in

caging, temperature, humidity, lighting, and sanitation. Manufactured diets and other feedstuffs are nutritious and scientifically determined to meet species requirements. The AWA and AWR require psychological enrichment for nonhuman species and an exercise plan for dogs. The AWA and AWR permit exemptions to these requirements for scientific purposes if sufficiently justified in the protocol and approved by the IACUC. Coleman and Novak (2017) discuss objectives, challenges, and benefits in developing an environmental enrichment plan for nonhuman primates.

The *Guide for the Care and Use of Laboratory Animals* discusses the use of environmental enrichment to enhance the welfare of all species (National Research Council 2011). Enrichment can be categorized as animate (human, conspecific) or inanimate (toys, feeding-interactives, housing, interactive-structures) (Ellis 2009). Most animal cognition studies routinely use enriched housing because sterile environments are known to inhibit normal brain function and development, whereas enrichment enhances normal brain function and development. Animals become better research models if allowed to develop normal cognitive function through enrichment (Morris et al. 2011). One concern with enrichment is neophobia, which is a negative response to novelty. Neophobia can affect both behavioral and immunological responses. For example, circulating cortisol levels are frequently used in animal cognition studies. Cortisol levels are particularly sensitive to changes in environment, circadian rhythm, and social interaction. Care must be taken to minimize the effects of stressors, including those caused by neophobia, on research outcomes. One technique of reducing neophobia is to apply positive reinforcement training to acclimatize the animals to enrichment materials.

Social species are often pair or group housed to encourage positive species-typical behaviors. Gilbert and Baker (2011) found that social contact among rhesus macaques decreased stress and adverse physiological effects and thus may improve research outcomes. However, Tardif et al. (2013) suggest that social housing may create problems in research due to frequent separation and reintroduction during research projects.

Hawkins (2014) reviewed the issues and effects of social and single housing on animals used in biotelemetry studies. This author presented the pros for social housing (lower stress, lower negative behaviors) and the cons (risk of radio interference, injury, or equipment damage).

Fillman-Holliday and Landi (2002) and Weed and Raber (2005) reviewed the often contradictory findings of the effects of enrichment on research results. They pointed out that environmental variability across experimental and control groups can influence physiological responses within experiments and create more noise in the data. A protocol should be planned carefully to meet species-specific social needs, and it should take into account a cost-benefit analysis weighing best housing, enrichment, and scientific goals. Part of the role of the attending veterinarian is to evaluate these elements and, where possible, offer assistance through suggested alternatives.

In some types of studies, research subjects are not housed in the laboratory but instead live in homes, animal shelters, and zoos (Horowitz 2014; Plotnik et al. 2014; Dale 2010). There is some risk of producing noise in the data due to variability in environment, although evidence suggests that this is much less of a problem than previously thought (Horowitz 2014). Certainly, it is more complex for the IACUC to evaluate such living circumstances for standards of care. Animals maintained outside the research environment are subject to considerable differences in nutrition, exercise, socialization, activities, etc. To accommodate these studies, creative thinking is necessary by both the researcher and the IACUC. For example, pets have been volunteered by owners for a number of veterinary and neuroscience procedures, including blood analyses and functional magnetic resonance imaging (fMRI). Pet dogs have been successfully trained to lie still during fMRI procedures without sedation (Andics et al. 2014). In another example, a study on spatial cognition and diet was conducted on dogs recruited from local shelters (Craig et al. 2012). Dogs meeting specific size, sex, and age criteria were removed from the shelters and kept in professional boarding facilities (not laboratories) for the duration of the study. All dogs were maintained on specific diets, were

exercised twice daily, socialized in groups in environmentally enriched yards, and tested in a radial arm maze. As part of the socialization experience, dogs were given basic obedience training in preparation for their adoption at the study's end. This study was evaluated and approved by the IACUCs of the collaborating organizations – the university's and the pet food company's.

## **Occupational Health and Safety in Animal Activities**

The PHS Policy and the *Guide for the Care and Use of Laboratory Animals* require that institutions offer an occupational health and safety program for personnel working with animals (United States Department of Health and Human Services 2015). The IACUC therefore has the responsibility to consider how human, animal, and community safety can be maintained in the conduct of animal activities. Prior to protocol review, risk assessments by safety personnel identify the hazards related to the kinds of animal activities proposed. Such hazards include injuries inflicted by animals (e.g., bites and scratches), infectious agents (zoonotic or experimental), chemical substances, ionizing radiation, temperature extremes, equipment, and poor ergonomic practices. Research in the field enlarges the range of safety issues, as personnel could become injured or ill due to, for example, falls and sprains, contact with poisonous plants, bites by venomous snakes, zoonotic diseases from biting insects, and so on. Safety equipment and practices may be recommended for each type of activity, and study personnel may be referred to the occupational health program for medical prophylaxis, such as immunizations. Personnel are not required to participate in their institution's occupational health and safety program, but those who decline may be not permitted to take part in the animal activities.

## **Protocol Review Outcomes**

The IACUC has two methods by which it may review an animal use protocol: full committee

review or designated member review. Full committee review takes place by a convened quorum and may result in approval, requirement for modifications (to secure approval), or withholding of approval. Designated member review is performed by one or more members selected by the committee Chair, provided that no members called for full committee review. Designated member review may result in approval, requirement for modifications (to secure approval), or referral to the full committee for review (in lieu of withholding approval). Regardless of the method for review, provisional or conditional approval of a protocol is never allowed. Furthermore, the investigator is not permitted to begin animal work before receiving IACUC approval.

## **Ongoing Oversight of Approved Protocols**

The IACUC has the responsibility for ongoing oversight of animal activities, which may include continuing protocol review, laboratory inspections, and observations of animal care and research procedures. To ensure optimal compliance, many institutions undertake a higher-level process known as post-approval monitoring, in which compliance staff inspects study procedures to verify that animal use is conducted according to the approved protocols and that animal-related records are thorough and accurate. This process helps investigators ensure their research meets regulatory requirements. Often, post-approval monitoring is focused on high-risk studies, for example, those involving surgery or causing unalleviated pain or distress in animals.

## **Changes to Approved Protocols**

When significant changes are needed in an approved protocol, an amendment must be submitted to the IACUC for review and approval. Significant changes are those that may have a negative impact on animal welfare. Examples include: a new principal investigator; a procedure resulting in greater pain/distress and invasiveness;

changing a surgery from nonsurvival to survival; a housing location that is not IACUC approved; different animal species; new study objectives; and heightened risk to personnel safety.

Some significant changes to approved procedures in a protocol may be handled administratively without an amendment (and therefore without further IACUC review) provided that specific requirements are met (National Institutes of Health Office of Laboratory Animal Welfare 2017b). A critical requirement is the IACUC's approval of guidance, such as a policy or SOP, describing the significant changes allowed and their scope. Without preexisting IACUC-approved guidance, a protocol amendment would be required. One change permitted administratively is increasing animal numbers above what was specified in the approved protocol, so long as the increase is in alignment with the IACUC guidance. In a process known as veterinary verification and consultation (VVC), the IACUC can authorize a veterinarian to allow specific types of changes in: anesthesia, analgesia, sedation, or experimental substances; euthanasia by any method approved in the AVMA Guidelines for the Euthanasia of Animals; and duration, frequency, type, or number of procedures performed on animals. The veterinarian verifies that the proposed changes comply with the IACUC guidance and are appropriate for the specific situations and animals. VVC does not permit the addition of new procedures to the protocol, as these would require an amendment.

## Noncompliance

Any deviation from an animal uses protocol is handled as a noncompliance and can potentially result in suspension of the study. The institution is required to notify the USDA, when the IACUC suspends an animal activity (United States Department of Agriculture 2017a). The institution is also required to report to OLAW any suspension of an animal activity as well as any serious or continuing noncompliance with the PHS Policy or the *Guide for the Care and Use of Laboratory Animals* (United States Department of Health and

Human Services 2015; National Research Council 2011). Moreover, OLAW reports to the USDA incidents it perceives as possible violations of the AWA and AWR. Violations will be investigated by the USDA, can be prosecuted in a court of law, and may incur large financial penalties and the suspension of registration as a research institution. Collectively known as enforcement actions, these may damage the institution's reputation because they are made public via the USDA website. They can also jeopardize the investigator's privilege of conducting research at that institution if funding support is terminated as a result of the violation or if the institution bars the investigator from using animals in order to minimize research risks.

## Conclusion

Supporting animal welfare and minimizing pain and distress are major considerations through every phase of an animal's care and use in science – procurement, housing and feeding, study procedures, and euthanasia. All personnel, including researchers, the IACUC, and animal facility staff, must collaborate to best support animal welfare while meeting scientific goals.

## History of Defining Imitation

Historically there has been little agreement on which behavioral or cognitive phenomena constitute imitation in animals. For example, because the term imitation is frequently used colloquially, some scientists have used the word in a loose sense when referring generally to social learning mechanisms. On the other end of the spectrum, some consider imitation to be a complex ability that is likely rare or nonexistent in nonhuman animals. Indeed, this problem of operationalizing imitation has roots in the work of early proponents of evolutionary approaches to behavior and is still frequently discussed in contemporary writings.

When Charles Darwin's protégé, George Romanes, published his famous collection of anecdotes on animal behavior in 1882, descriptions of imitation-like feats abounded. However, no definition of imitation was provided. Instead, Romanes reported a panoply of seemingly imitative behaviors, ranging from specific case-studies (for example, the cat that adopted the food-begging habits of a cohabiting terrier), to more general observations (for example, how some species of birds model their vocalizations on environmental noises). Romanes' anecdotal approach to animal behavior sparked general interest in the topic of the animal mind, but also encouraged others to consider more conservative

interpretations of seemingly intelligent behavior in animals; for example, Lloyd Morgan proposed his famous canon, where he emphasized that animal behavior should not be interpreted as the outcome of "a higher psychological faculty," if it can instead be explained by "lower" processes (1894, p. 53). And indeed later, Morgan (1900) made an effort to categorize various imitative-like phenomena, highlighting the distinction between instinctive and deliberate forms. Instinctive imitation was said to occur in cases where an observed behavior acts as a releasing stimulus for that same behavior in a conspecific (describing what is generally referred to as behavioral contagion today; Hoppitt and Laland 2013), while for deliberate imitation to occur an animal was required to possess an intention to imitate a behavior. Interestingly, Morgan compared deliberate imitation in nonhuman animals to the type of imitative ability demonstrated by human children (*Homo sapiens*), framing imitative behavior in an anthropocentric manner.

Another pioneer in the field of animal behavior, Edward Thorndike, provided further guidance on how imitation in animals should be approached, supplying the first definition of imitation. He described imitation as "learning to do an act from seeing it done" (Thorndike 1911). To this day, many scientists use this broad definition as the basis for discussing imitation, before applying a number of operational caveats, a trend that Thorndike himself instigated. Thorndike was clear about a number of behaviors that did not qualify as imitation. For example, bird song was considered a special case, as vocal imitators did not seem to possess more general imitative capacities, and because, in the auditory domain, the perceptual overlap that is available to vocal imitators, between performance by self and other, is considerably greater than the overlap in the visual domain afforded to imitators of action. While today our understanding of both vocal and physical imitation is significantly enriched, these areas of research are still largely independent of one another.

To be confident that an animal has demonstrated imitative ability, Thorndike suggested one must also rule out a number of so-called

pseudo-imitative processes (what we now know as non-imitative mechanisms of social learning). Following Morgan, Thorndike (1911) stressed that instinctive forms of action imitation are categorically different from true imitation and that some “simple acts” triggered upon observing a behavior (e.g., yawning) should also not be considered truly imitative (however, the distinction between “simple” and “complex” behaviors was not made explicit by Thorndike).

Distinguishing imitation from other social learning mechanisms, or this “definition-by-exclusion” approach, has been hugely influential in the field of imitation research both theoretically and methodologically. This approach, when complemented by the explanatory parsimony central to the school of comparative psychology spearheaded by Morgan and Thorndike, drove imitation research throughout the last century and largely still stands today. Influential writings on primate behavior published throughout the early and mid-twentieth century, for example, would often begin with descriptions of non-imitative phenomena. Yerkes and Yerkes (1929) explicitly highlighted mechanisms that did not constitute imitation (e.g., local enhancement) before discussing their observations of imitation-like behavior in chimpanzees (*Pan troglodytes*). The care in describing imitation in animals can also be found in the writings of Hayes and Hayes (1952). The Hayeses intentionally described the imitative-like behavior they observed in their home-raised chimpanzee Viki without formal classification or definition of imitation, allowing readers to draw their own conclusions about whether their observational and experimental findings justified an imitative description.

Work on non-imitative social learning mechanisms seems to be driven largely by the need to isolate imitation, and so discussion of imitation cannot proceed without some allusion to other social learning mechanisms (described extensively elsewhere in this Encyclopedia). Consider the following observation from the perspective of a researcher interested in imitation: “Shortly after observing a conspecific cracking nuts with a rock, a monkey approaches the same rock, now idle, and uses it to crack a nut.” A human observer

recording this event might conclude that a monkey learned to imitate this nut-cracking behavior, that is, the monkey learned to perform a behavior from seeing it done. But it could also be argued that the mechanism leading to the performance of the behavior was local enhancement; the monkey was merely attracted to the nut-cracking site through the presence of the individual, and the nut-cracking behavior was acquired through trial-and-error learning. Other mechanisms that could facilitate this nut-cracking behavior and confound the study of imitative ability include stimulus enhancement (the monkey was attracted to the rock and the nut), affordance learning (the monkey learned about the physical properties of the rock and/or nut), goal emulation (the monkey learned that a nut could be extracted from a shell), and response facilitation or contagion (the nut-cracking behavior was already in the monkey’s behavioral repertoire and was merely primed by observing the same behavior; note the distinction between response facilitation and contagion largely depends on whether priming is learned or innate; Hoppitt and Laland 2013). The thoroughness of the “definition-by-exclusion” approach has generated both a useful taxonomy of social learning mechanisms (e.g., Whiten and Ham 1992) and inspired ingenious methodologies. However, the definition of imitation is not limited to a description of what imitation is not. Once Morgan’s canon has been applied to the observation of an imitative-like behavior, there remains a number of possible explanations for what exactly has taken place cognitively. This extra level of analysis applied to imitation has traditionally tended to focus on how powerful imitation might be as a social learning mechanism.

## The Complexity of Imitation

Thorndike did not necessarily consider imitation an intelligent process, writing that “an imitative act could be performed quite unthinkingly” (1911, p. 79). However, he discussed imitation as a phenomenon that requires “reason,” and also explicitly made a distinction between complex and simple imitative phenomena. Today, cognitive

complexity is often considered central to imitation. At its most complex, imitation is defined as the ability of an animal to learn how to perform an action previously not present in its behavioral repertoire after seeing the action performed by another individual (Byrne 2002). The novelty criterion frames imitation as a significant means of learning new behaviors, but novelty is also difficult to operationalize. To know if an animal's behavior is novel, a researcher must compile a comprehensive list of all the previous behaviors an animal has performed, a logistically improbable feat in most cases. Also, upon reaching maturity an animal is likely to have already executed the vast majority, if not all, potential physical movements, rendering novel action, and therefore imitation, impossible. Thorpe (1963) applied a more liberal novelty criterion, describing imitation occurring when the copied act is either novel or *improbable*. However, while the improbability caveat bypasses the problem of identifying novelty, Thorpe did not clarify how exactly one should operationalize "improbable."

To overcome these empirical and theoretical limitations while maintaining a powerful role for imitation in learning new skills and abilities, a weaker novelty criterion has been proposed. Imitation could still facilitate novel behavior but not at the level of physical action. Instead, contextual imitation occurs when an animal learns how to perform actions already in their behavioral repertoire in novel contexts (Byrne 2002). Under this interpretation, imitation is still a powerful learning tool, allowing animals to exploit resources in new settings. It has also been suggested that novelty could be demonstrated when an animal learns how to combine familiar actions into a novel action-string, again emphasizing the role of imitation in learning (see production imitation, Byrne 2002).

But novelty is not the only way in which imitation has become cognitively loaded. Some have suggested that understanding the intentions or goals of the individual being imitated is central to "true imitation" (Tomasello et al. 2005). However, while this may be a sensible distinction to make theoretically, it also leads to empirical problems, since identifying intention reading in an animal is far from trivial. Indeed, other

mechanisms of social learning have been defined to specifically describe when an animal learns about the goals or outcomes of an action (e.g., emulation), rather than the action itself, so it may not be useful for researchers of imitation to consider these phenomena as one, at least not in an operational sense.

For others, imitation is more simply the matching of topographical features of behavior (van de Waal and Whiten 2012; Voelkl and Huber 2000). This approach captures the spirit of Thorndike's definition, as long as "act" is interpreted specifically to mean an animal's physical behavior, rather than the psychological processes that lead to the behavior or the effects this behavior may have on the environment. While other phenomena of social influence (for example, contagion) also require the matching of topographical features, as contagious acts are limited in number and stereotyped in form, they can be readily documented and ruled out when distinguishing a "truly" imitative act.

Action imitation, without novelty or intention-reading, is still thought to require considerable cognitive effort because of the "correspondence problem." The correspondence problem was described by Nehaniv and Dautenhahn (2002) as the difficulty faced by an observer in recreating an action that perceptually, cognitively, or motivationally corresponds to the actions of the model. Consider the difficulty faced by a dog attempting to imitate its human owner's action, say, opening a door. As paws and hands differ in many morphological features (e.g., arrangement of the phalanges), the dog is required to perform an action that perceptually corresponds little to what they have observed. A lack of perceptual correspondence is also problematic within species. When an animal observes the actions of another, the perceptual input rarely maps directly to the perceptual experience of observing oneself. Indeed, in cases where an action is completely unobservable, or opaque, to the animal performing the act (e.g., a facial expression), an imitator must recognize that the perceptual qualities observable in an action (e.g., a conspecific's frown) correspond to some specific muscle movements (e.g., constriction of the corrugator supercilii). This example represents

an extreme case in relation to perceptual correspondence; however, low levels of perceptual overlap occur across most cases of action copying. While it is unknown how imitators may solve this problem, some have suggested that the mirror neuron system, a subset of neurons that have been found to map sensory information about an action onto neurons linked to that action's performance, might help bridge the correspondence gap (Gallese et al. 1996). However, the link between imitation and mirror neurons is far from clear, and there is still no consensus on the cognitive processes that enable animals, humans included, to convert an observed action into a corresponding motor response.

Overall, while some may argue that the study of imitation has been muddled by conceptual discrepancies, the vigorous debates over the classification of imitation have ensured researchers are careful when interpreting and categorizing imitative-like behavior. Furthermore, this discussion has led to the development of a number of innovative methodologies that allow researchers to distinguish between varied social learning phenomena.

## Methods of Studying Imitation

As well as providing the first definition of imitation, Thorndike (1911) also pioneered the use of controlled experimental methods to explore imitative behavior. His studies of chicks, cats, dogs, and monkeys largely involved allowing a naïve individual to observe an experienced conspecific escape from a cage. The naïve animal would observe from either the same cage as the escapee or through some wire mesh, always able, if attentive, to observe the behavior of their neighbor. Thorndike noted the attentiveness of the observer, recording the number of instances that the naïve individual was orientated towards the experienced animal, and subsequently measured how long it took the animal to escape following repeated observations of the conspecific's performance (e.g., pulling a string to open a cage-door). Although his studies found little evidence that social demonstration led to quicker escape times

in comparison to individuals that had not received social information, one could also fairly criticize whether these methods even allow discrimination of imitation from other social learning mechanisms. As imitation is considered more cognitively demanding than other social learning mechanisms, conclusive identification of imitative learning in an experimental paradigm must rule out the possibilities of other mechanisms giving rise to the observed effect.

When housing animals within the same or adjacent enclosures, it is difficult to distinguish which exact mechanisms might lead to learning. However, while ineffective in distinguishing true imitation, this method has been used extensively to examine social learning abilities of animals more broadly. To more reliably evaluate the learning mechanisms at play in social arenas, the highly influential two-action method was introduced (Dawson and Foss 1965). The two-action method requires an apparatus that can be manipulated in two different ways; for example, a lever may be pressed to either the left or the right to receive a reward. If, upon observing an animal interact with this apparatus using one of the two methods (e.g., observing an animal move a lever to the right rather than the left), the observer is more likely to perform that same action when compared to an individual who had not experienced a social demonstration, it can be concluded that some form of social learning has taken place. However, again, the use of this method in many cases does not explain whether the animal has learned specifically about the actions used upon the apparatus, or rather the affordances of that apparatus. Nonetheless, the two-action method has been successful in identifying more general social learning phenomena in a range of species. To control for some of the limitations of the two-action method, automated apparatuses, or "ghost apparatuses," have been used in some studies of social learning. These ghost apparatuses allow an experimenter to reveal the affordances of an object (for example, the movement of a lever) without a social agent acting upon the manipulanda. If animals can learn the actions necessary to operate the apparatus in only the cases where a social demonstrator is present, it is

argued that action imitation is likely to have driven this behavior, rather than other phenomena.

A variation of the two-action method has been used to specifically examine imitation of actions performed by different body parts. Under this method, researchers train model animals to interact with an apparatus using one of two different body parts. For example, one model might be trained to open a canister with its mouth, while another would be rewarded for using its hand or paw to achieve the same goal. The model then demonstrates the trained actions in the presence of naïve conspecific observers before the observers themselves are given the opportunity to interact with the apparatus. Following the social demonstration, if the observer uses the same observed action more often than the alternative, then body-part imitation can be said to have taken place. Studies using this method have identified evidence of body-part imitation in primates (e.g., *Chlorocebus pygerythrus*, van de Waal and Whiten 2012; *Callithrix jacchus*, Voelkl and Huber 2000), as well as some species of birds (e.g., *Coturnix japonica*, Akins and Zentall 1996), and those who favor the definition of imitation as action matching have described these findings as evidence of true imitation.

Another method of identifying imitation of actions is the “do-as-I-do” paradigm. This procedure requires an experimenter to first train an animal to perform a number of actions on command. Subsequently, the trainer performs one of the trained actions, introduces a cue or command signal (e.g., “do this”), and rewards an animal only if it performs the same action. This training procedure of action shaping and positively reinforced copying is repeated for a number of actions, and finally some novel untrained actions are introduced. The question is whether animals are able to generalize their training such that they respond as if they recognize the cue as an instruction to imitate. It has been argued that this is the most reliable method of identifying intention to imitate, of the sort proposed by Morgan, as to succeed on this task it is thought that the animal must have conceptualized what it means to imitate. This method has successfully identified

imitative capacity in enculturated apes and dogs (e.g., *Pongo pygmaeus*, Call 2001; *Canis lupus familiaris* Topál et al. 2006), but not monkeys (*Cebus apella*, Frigaszy et al. 2011). More recently this method has been adapted to test if beluga whales (*Delphinapterus leucas*) can learn to imitate conspecifics, through the use of a “do-as-they-do” task with promising preliminary results (Abramson et al. 2017). The controlled use of the “Do-as-I-do” paradigm and two-action method have added empirical validity to less systematic bodies of evidence of imitative behavior.

Experimental research is clearly the most valid and reliable way of understanding the abilities of animals, but it is worth highlighting that some of the most compelling evidence of complex imitative ability is anecdotal in nature. Viki, a chimpanzee raised as a human child by Catherine and Keith Hayes, for example, seemed to imitate a number of human-like behaviors. One of the most compelling examples involved Viki taking a tube of lipstick, applying the color to her lips in front of a mirror, then, pressing her lips together before rubbing the color with her fingers (Hayes and Hayes 1952). According to the Hayeses, this behavior was untrained, unrewarded, but nonetheless resembled closely the sequence of behaviors Viki would have observed performed by a human. Russon and Galdikas (1993) reported a number of instances of orangutans (*Pongo pygmaeus*) imitating human activities including fire-preparation behavior, the building of a bridge across a river, and painting. Again, each behavior was unrewarded and was performed unprompted. These cases of human-like behavior performed in novel contexts and the novel combination of behaviors certainly seem to meet many of the more restrictive novelty or improbability criteria proposed to set imitative behavior apart from other forms of social learning. Anecdotes of interspecies imitation of this sort, where the model is not human, is rare, but one convincing case involves a dolphin (*Tursiops aduncus*) imitating the swimming technique of a Cape fur seal (*Arctocephalus pusillus*) that was housed in the same pool; the dolphin was observed to propel itself through the water using flipper movements

rather than dolphin-typical fluke movements (Taylor and Saayman 1973).

These anecdotal accounts paint a richer picture of the possibility of complex imitative abilities of large-brained mammals; however, they also lack the rigor of the experimental methods described above, making it difficult to assess specifically which mechanisms might allow these behaviors to arise. Nonetheless, these accounts provide fascinating examples of the complex social abilities of some animals when allowed to interact without limits placed on their behavioral repertoire, as is often the case in experimental settings. Importantly, these observations can also enrich and inspire experimental work. For example, Hayes and Hayes (1952) developed the “Do-as-I-do” method, in an effort to more carefully study the imitative behaviors that they already observed Viki perform. It is worth noting that the majority of these anecdotal reports involve primates that have had extensive interactions with humans, in some cases raised by humans. While spontaneous imitation of complex behavior is less common in non-enculturated animals, it is unclear whether this is because human interaction drives the development of imitative behavior or merely facilitates the collection of anecdotes. A chimpanzee performing a typically human behavior (e.g., applying lipstick) will offer more compelling evidence of imitation than would anything involving common species-typical behaviors (e.g., a specific foraging behavior like nut-cracking). The experience potentially necessary for imitative behavior to develop is well worth exploring, and we have a lot to learn about how imitative phenomena may be facilitated by human interaction.

While great steps have been made in understanding imitation and other social learning mechanisms through the use of varied methodologies, it is worth remembering that no one method will be able to paint a complete picture of this phenomenon across all taxa. Anecdotal claims will continue to inspire more careful observation of behavior as well as insightful experimental designs, and together, these methods will continue to help researchers better understand a range of imitative phenomena.

## Mirror Neurons and Imitation

To understand the mechanism of imitation, researchers have spent considerable effort exploring neural substrates that have been linked to imitative behavior in primates. Mirror neurons, first discovered in the F5 region of a pigtailed macaque’s (*Macaca nemestrina*) parietal lobe by researchers in Parma (Gallese et al. 1996), may provide the neural foundation that allows an animal to solve the “correspondence problem.” Neurons sampled in the premotor area have been found to fire when macaques perform an action (i.e., grasping a peanut), and also when the monkey observed the researcher perform the same action. These initial studies described neurons with both visual and motor properties, single cells that could represent information about another’s actions in egocentric terms. A thorough exploration of this neural subset was published in 1996, outlining multiple properties of these cells (Gallese et al. 1996). For example, these neurons fired when monkeys observed an experimenter acting upon an object but did not fire when the object or the action were presented in isolation, suggesting some functional role in goal directed behavior. Furthermore, while most neurons were active for specific motor actions (e.g., a power grip or precision grip), some neurons were more sensitive to the goal of the action, firing irrespective of effector (i.e., three sampled neurons fired when the experimenter picked up an item using either the hand or mouth). Subsequent studies of single neurons have explored a range of properties of these macaque mirror neurons (for a review see Kilner and Lemon 2013), and while it is likely that a similar system is present in other primates, currently, the only other evidence of a homologous system has been reported in humans (Iacoboni et al. 1999; although there is some preliminary evidence that a similar system may be present in the common marmoset, Suzuki et al. 2015). Although the function of mirror neurons has been disputed, a parsimonious interpretation suggests mirror neurons play a role in recognizing the actions of others, and so while the primary function of mirror neurons may not be directly

related to imitation, by facilitating action recognition these neurons could still contribute to resolution of the correspondence problem by recruiting additional brain regions.

## The Origins of Imitation

Considering imitation from the comprehensive ethological perspective championed by Nikolaas Tinbergen (1963) requires consideration of a number of different factors. However, it seems that empirical work on imitation has been disproportionately concerned with understanding the distribution, or phylogeny, of imitative ability throughout animals, with a particular focus on the primate clade. The mechanism of imitation has also been studied extensively, specifically when it comes to understanding which social and nonsocial stimuli are necessary for imitation and other social learning phenomena to be observed (see the discussion of methods above). Furthermore, much effort has also been expended to explore potential neural mechanisms of imitation. On the other hand, the remaining Tinbergian questions of ontogeny and adaptive function are currently not well understood in relation to imitation.

While it makes logical sense that the ability to imitate actions would be adaptive in facilitating the learning of new skills more quickly when compared to trial-and-error learning, it is difficult to find empirical support for this assumption (as is the case for many hypotheses concerning adaptation). However, while difficult to empirically demonstrate adaptive benefits, computer-based models of foraging strategies conclude that an ability to exploit social information is highly adaptive (e.g., Rendell et al. 2010). Theoretically, then, it is likely that there has been some selective pressure on social learning mechanisms like imitation. Indeed, some theories of brain evolution propose that sociocultural pressures may have driven encephalization in primates and other large-brained species. This cultural intelligence hypothesis proposes that social learning mechanisms may lead to more complex traditions and culture, which in turn place greater selective

pressure on these mechanisms (Whiten and van Schaik 2007). This theory complements other perspectives on social drivers of intelligence in animal societies but places a stronger emphasis on the domain of social learning. While theoretical and correlational work provide at least some insights into the potential adaptive value of imitative behavior (see Whiten and van Schaik 2007), in contrast, the ontogenetic roots of imitative behavior remain underexplored from any angle. Indeed, it is possible that misunderstandings about the complementary roles of adaptive and ontogenetic processes may have unintentionally stymied research on development. That is, if researchers assume that imitation is an evolved adaptive capacity, it might also be assumed that this entails hardwired processes largely independent of individual variation in experience or learning opportunities. As a consequence, developmental processes may be overlooked.

One of the most debated areas in imitative research is the question of whether an ability to imitate actions is present at birth in some species. Much of the discussion concerning both mirror neurons and imitative ability seem to implicitly suggest that imitation is an evolved capacity, with observations of imitative ability in infant primates presented as evidence of this fact. Imitative ability has been identified in the infants of a number of primate species including rhesus macaques (*Macaca mulatta*), chimpanzees, and humans (for a review see Oostenbroek et al. 2013). However, it is unlikely that these phenomena are responsible for all imitative behavior in primates, especially given that many of these early imitative behaviors are only present for a restricted range of actions (e.g., in one case only two of four actions tested were imitated by infant macaques; Ferrari et al. 2006), and are only present during very specific time-windows (e.g., imitation of actions by infant macaques only occurred on their third day of infancy; Ferrari et al. 2006). One mechanistic model proposed to explain this phenomenon is the intermodal mapping model of imitation (AIM) which describes an innate process that matches the representation of observed motor actions with proprioceptive feedback from the performance of the same action (Meltzoff and

Moore 1997). It is conceivable that the mirror neuron system is the neural mechanism that supports this intermodal matching system; however, there is currently no empirical evidence in support of an innate mirror neuron system.

Even if an innate action-matching capacity exists in animals, it is likely that later experience also shapes imitative ability. One developmental view of imitation, the Associative Sequence Learning (ASL) hypothesis, proposes that through repeated experience of observing and performing actions in social contexts, an animal begins to associate sensory representations of specific actions with the motor representations of the same actions (Heyes and Ray 2000). Consider a flock of birds that upon reaching a foraging site begin manipulating the soil with their beaks to extract insects or grains. According to the ASL view, if this experience is repeated, an individual will learn to associate their own pecking behavior with the sensory experience of their group mates performing the same behavior. Building up specific associations between observed and performed actions may then in the future facilitate action imitation. These sensory-motor associations could be formed when environmental factors (like foraging opportunities) synchronize behavior but also when observing one's own actions, and in some species, they may be created when being imitated by parents or conspecifics. This approach posits that the correspondence problem can be overcome through associative process that are widespread among animals and questions the level of cognitive complexity necessary for an animal to match the behavior of a conspecific. Support for this approach is found in studies where imitation biases are reduced or eliminated by providing animals with sensory-motor experience that would disrupt previously formed associations. For example, in one case, dogs (*Canis lupus familiaris*) were rewarded for opening a door with their mouth after seeing a human open the door with their hand, and vice versa. These dogs were later found to struggle to learn an imitative stimulus-response association, when being trained to open a door with the same effector, compared with dogs that had not received the prior incompatible training (Range

et al. 2011). These effects have been also shown in humans, and capuchin monkeys (*Sapajus sp.*), demonstrating that imitative effects are indeed malleable in response to sensory-motor experience in some species (O'Sullivan et al. 2017), but overall, much more work is needed to understand how these experiential accounts can explain imitation of complex actions in animals.

It is important to remember that evolved and developed capacities interact and overlap, and that there is likely no purely innate or learned explanation for imitation, as is the case for most behaviors. An open-minded approach is essential to fully understand the origins of imitative behavior, and this should also extend beyond a primate-centric view of imitation. Evidence of imitation has largely emerged from work with primates, but it may be that by labelling imitation, a complex mechanism, research efforts have focused too extensively on animals considered to possess a cognitive toolkit similar to our human one. A truly comprehensive evolutionary approach to imitation, on the other hand, would stress how environmental and social pressures acting upon imitative capacities should function across animal species and that much of the experience posited to facilitate action imitation is potentially available to members of a range of social species throughout development. With this in mind, future efforts to explore imitative ability, defined as morphological matching, can avail of a wide range of species and methods to develop a more complete picture of this ability.

## Imitation in Humans

The phylogenetic distribution of imitative ability is an open empirical question, but humans are certainly imitative, regardless of how the term is operationalized. Studies of neonatal imitation suggest humans may have some innate disposition to imitate action from birth (see Oostenbroek et al. 2013). However, evidence of neonatal imitation in nonhuman primate species that are poor imitators when tested in later development (Ferrari et al. 2006), and indeed, uncertainty over the generalizability of imitative ability in human

infancy (Oostenbroek et al. 2013), makes it difficult to draw concrete conclusions about how neonatal imitation may facilitate imitation in later life. Focusing on the ontogeny of imitative behaviors in human children, developmental psychologists have described how progressively more complex abilities develop throughout the first years. For example, children imitate actions that make sounds before they can produce opaque actions (Jones 2007), and by three years, the propensity for imitation in any guise (whether intentional, improbable, etc.) is highly developed in humans (Horner and Whiten 2005; Jones 2007). Recent studies show that the motivation to imitate in adults and children even leads to the copying of causally irrelevant behaviors in cases where it seems obvious that the completion of a task (e.g., opening a box) does not require the additional actions (e.g., unnecessary tapping on the box-lid; Horner and Whiten 2005). Furthermore, it seems that this “over-imitation” is also uniquely human. Studies that have directly examined the imitation of actions unnecessary for a task’s completion across both human children and apes have to-date found that apes will perform actions relevant to the task’s completion, ignoring additional demonstrated behaviors, while children will imitate more comprehensively all actions whether relevant to the task’s completion or not (e.g., Horner and Whiten 2005). Indeed, it has been suggested that the human species’ ability to accumulate suites of progressively more complex socially learned behaviors over time might be attributed to these tendencies for high-fidelity social learning (Acerbi and Tennie 2016).

Imitation is largely defined in the context of learning; however, in humans, imitation is also linked to other social variables. In both adults and children, the matching of specific behaviors (e.g., body postures, behavioral movements, etc.) has been linked to other aspects of sociality (e.g., affiliation). For example, in one study, adults who were imitated by an experimenter’s confederate reported liking the person more than if not imitated (Chartrand and Bargh 1999). Further, there is evidence that this link between sociality and imitations is present early in development, as 18-month-old children were found to be more

likely to help individuals who had previously mimicked them (Carpenter et al. 2013). One study in nonhuman primates demonstrated that capuchin monkeys preferred to interact and attend to humans who had imitated them (Paukner et al. 2009), but it is unclear how generalizable this relationship is in either capuchins or other primate species. Indeed, the link between instrumental and socially motivated imitation has yet to be fully understood in humans. Nonetheless, whether driven by learning, affiliation, or other factors, the imitative phenotype is obvious in humans from an early age. On the other hand, and as discussed above, the identification of imitation in nonhuman animals depends on its operationalization, and some of the most conservative definitions rule-out its presence in most species. It is difficult to conclude, however, whether this difference is one of degree or kind; the disparity is great, but this empirical question is yet to be answered.

## Summary and Conclusions

Work in the late nineteenth century by early proponents of evolutionary approaches to cognition began a tradition of exploring imitation, a term whose meaning still defies consensus. However, the existence of a rich literature concerned with understanding the meaning of animal imitation ensures that researchers today are careful in their use of the term, thoroughly and explicitly highlighting what imitation means to them. To some, imitation occurs with an entirely novel behavior is learned through observation; to others, an old behavior learned to be performed in a new context qualifies. Imitation might be described as a chain of old behaviors produced in a novel order, or true imitation might be most simply, the matching of morphological topography.

If imitation is considered to require novelty or intention, then currently it may only be evidenced through the Do-as-I-do task in a few species. However, if imitation is defined more liberally as the matching of actions, this phenomenon is observed across a range of social species including dogs, apes, monkeys, and birds. The best

efforts taken to methodologically isolate imitative ability are commendable in offering great insight into the eliciting stimuli and contexts in which social learning takes place, but these methods are also limited by the constraints of experimental control, which often entails the removal of the full range of potential social and nonsocial inputs. Imitative behaviors are likely to occur in conjunction with enhancement effects, emulation, affordance learning, and other phenomena; a tapestry of mechanisms scaffolding each other and facilitating adaptive behavior in complex social environments. Learning the affordances of an object is likely to canalize specific actions, while the capacity to match behavior likely facilitates learning about object affordances. How imitation works in conjunction with other mechanisms has yet to be properly understood, and this is a noble goal for the future field of imitative research. Many years have passed since Romanes and Thorndike first considered the questions of animal imitation, reaching very different conclusions informed by their respective methodological paths. Today, there are lessons to be learned from both pioneers. Both empirical rigor and careful observation continue to perform critical and complementary roles in elucidating animal abilities for learning to do, from seeing done.

## Immanuel Kant

Martin Schönfeld

University of South Florida, Tampa, FL, USA

**Kant, Immanuel** (1724–1804). German philosopher, leading mind of the Enlightenment, and one of the most influential thinkers of civilization. He contributed to epistemology, ethics, and political theory, as well as to natural philosophy (the partly speculative precursor of the natural sciences). Kant remarked on animals in ethics, metaphysics, and natural philosophy. In ethics, he formulated human-centered arguments against animal cruelty; in metaphysics, he determined the ontological status of animals; and in natural philosophy, he was the first Western thinker to give a systematic account of material self-organization that implies a human descent from animals. A problem, which affects several of his positions, is that Kant lived at a place and in a time that imposed theological constraints on animal studies.

### Anthropocentric Animal Ethic

Kant's most influential contributions are in the field of practical philosophy. Well-known are his arguments for decolonization and his case for a United Nations in political theory, and a principle of action to assert human rights, the Categorical Imperative in ethics. In *Groundwork to the Metaphysics of Morals* (1785), Kant gives several formulations of the Categorical Imperative; by the second formula, one should treat humanity, whether in one's own person or in that of another, always as an end and never as a mere means only (cf. Kant, *Gesammelte Schriften*, 4:429). Humans are autonomous beings because of their potential for independent rationality. This capacity to act according to judgment reveals humans as self-governed organisms, and in this sense they are ends in themselves. The Categorical Imperative is a demand for human rights. It is not a demand

for animal rights; however, for animals, in Kant's understanding, cannot act on judgment and are therefore heteronomous, governed not by reason but by other drives, such as instincts and inclinations.

According to a student transcript, *Moral Philosophy: Collins's Lecture Notes* (1784–1785), Kant taught that since humans but not animals are capable of judgment, only the former have moral standing, and all our duties are duties to humanity. To animals, we have no obligations, at least not directly (27:459). Nonetheless, Kant acknowledges that there are clear constraints on how to treat animals. Animal cruelty is wrong; first, because animals are sentient, since we see “how greatly they care for their young,” and second, because a person who mistreats animals “is also no less hardened towards men” (27:459). Animal cruelty is a wrong against humanity, for such misconduct creates liabilities for other humans. Following Thomas Aquinas, Kant concludes that the duty not to mistreat animals is a duty *about* animals but not owed *toward* them; duties to animals are indirect duties to humanity (27:460).

### Animals Have Souls

In his metaphysics class, according to student notes, *Metaphysics L<sub>I</sub>* (ca. 1775), Kant distinguishes the structure of reality into types. One distinction obtains between material and immaterial beings; that is, between nonlife and life, or “inanimate” and “animate” nature (28:274). Matter as such is inanimate, but there are also immaterial beings, and these are minds. That animals have material bodies does not make them “mere machines or matter; rather, they have souls” (28:274). “Soul,” for Kant, is an immaterial being that interacts with the body, is constituted by such interaction, and ceases to be when the body dies (28:273–274). “Spirit,” by contrast, would be a speculative immaterial being able to cognize in disembodied form. Empirically, we distinguish nonlife from life through

movement – if something moves by itself, it is alive and thus endowed with a soul. “To the extent matter is animated,” Kant notes, “it is *ensouled*: a principle of life underlies animals, and that is the soul.” (28:275). A question he wrestles with is how to distinguish animal minds from human minds. In the metaphysics-lectures, his answer remains ambiguous. On the one hand, animals possess cognition in that they are “beings that have mere sensibility and power of representation” (28:274). On the other hand, it is unclear how animal cognition compares to human cognition; this issue highlights “the limits of reason” and makes us “acquainted here with our ignorance” (*ibid.*).

In his *Lectures on Philosophical Encyclopedia* (1775–1782), he believes to have isolated a qualitative difference between animal and human souls. While both types of souls are sentient (‘sensibility and power of representation’), human souls are endowed with “consciousness,” which is “the main and nearly the only difference . . . but this is also so large that it cannot be replaced by anything” (29:44). However, strictly speaking, this qualitative difference is only a difference in time, for what makes these remarks interesting is that Kant also argued for the gradual emergence of qualitatively new properties in the course of nature’s self-organization.

## Evolutionary Descent and Material Emergence

In *Critique of the Power of Judgment* (1790), Kant suggests that humans have descended from animals; that animals evolved from primitive life; and that primitive life has self-organized from interplay of matter and energy (5:419). The evidence for a “system” or “principle of generation” lies in “the agreement of so many genera of animals in a certain common schema” or in “an analogy of forms.” (5:418). While he concedes that this sought-for principle of generation has not been found yet and that settling this issue must await further scientific progress, the evidence is sufficiently suggestive to “strengthen the suspicion of a real kinship among [animals]

in their generation from a common proto-mother [*Urmutter*], . . . from human beings down to polyps, and from this even further to mosses and lichens, and finally to the lowest level of nature that we can observe, that of raw matter: from which . . . the entire technique of nature . . . seems to derive” (5:419).

In the early, pre-critical treatises, *True Estimation of Living Forces* (1747), *Universal Natural History* (1755), and *Physical Monadology* (1756), Kant gives a speculative account of nature’s self-organization. Self-organization begins dynamically with energy (1:17) and structurally with polarity. For the logic of being, polarity means there is no simple first principle of ontology. Instead, Kant argues in *New Elucidation* (1755), the first principle is complex: a binary schema of negative and positive combined as contradiction (1:388–390). In *Living Forces*, he explains how energy stretches out as space, and how space weaves a web of power points (1:22–24). In *Physical Monadology*, he theorizes how spatial power points are dynamic sources of matter: polarized in attraction and repulsion, any point source radiation expands a tiny dimensional manifold, an impenetrable, repellent “activity sphere,” which accretes with other such energy bubbles into elementary form that constitutes material particles (1:481–484). In *Universal Natural History*, he reasons how a cosmic fog of scattered particles contracts into clouds that evolves into galaxies, star systems, and planets (1:254–256, 263–269). Planets, once formed and cooled (1:199–200), spawn biospheres with plants, animals, and humans (1:352–353). How life unfolds to higher levels of self-organization, Kant surmises, is due to the varying density of matter; the less dense the material substratum is, the more highly evolved organisms will be, up to a step ladder of conscious beings (1:358). Consciousness, he speculates, would have to be ubiquitous in the cosmos, and humans, far from being the pinnacle of creation, occupy only the middle rung on the ladder of beings (1:359).

Instead of self-organization or emergence, Kant uses the phrase *Auswicklung der Natur*, literally “out-wrapping” or “unfurling” of nature (*cf.* 1:201, 1:226). This is Kant’s Germanized

form of the Latin *evolutio* (cf. also 16:324). The Latin term denotes the opening of book scrolls. The image is that the book of nature is like a gradually unfolding scroll, disclosing steadily more lines of information. (Kant's term for complexity is *zusammengesetzte Richtigkeit*; "compound soundness," cf. 1:226). The emergence of complexity – from matter to life, from life to animals, and from animals to consciousness – is driven by "a general world-spirit, an intangible, pervasively efficacious principle, which is the secret engine of nature" (1:203). Although Darwin was the first to put the hypothesis of human evolution in scientific form, Kant was the first to put it in systematic conceptual form. But since Kant conceived of evolution as the self-organization of order from chaos and of complexity from simplicity, he is less a predecessor of Darwin and more a precursor of Prigogine's work on dissipative structures.

### Censorship and Politicization of Evolution

The historical context of Kant's reflections on animals was generally repressive. There was little freedom of speech on such issues before the division between church and state was complete, although by the 1780s, one could be more open than in the 1750s. In early modern Europe, ethical and metaphysical questions on animals – their moral standing, and their relation to humans – had been decided by the churches. Deviation from Biblical doctrine was branded as heresy, and dissent was a punishable offense. As the Enlightenment (1680s to 1780s) proceeded, punishments grew more lenient but oppression remained. Notions such as animal rights, animal cognition, and human evolution were rated as blasphemous. Although witch-hunts had ceased in Prussia before Kant was born in 1724 (executions stopped in 1701; trials ended in 1714), persecutions elsewhere in German lands lasted well into the 1770s. The enforcement of religious orthodoxy had chilling effects. Academics in support of animal cognition had to do so secretly to avoid unemployment or deportation.

In Kant's day, thinkers known for dissent from doctrine were referred to as free-thinkers, or Spinozists.

A further complication concerns the status of evolutionary ideas in natural philosophy. The evolutionary hypothesis had been brought to Europe from China by Jesuits in reports of East Asian belief-systems such as Daoism. Evolution of life from nonlife, and emergence of complexity through polarity (*yinyang*) are key ideas in Daoist metaphysics (cf. *Daodejing* c. 42 and *Zhuangzi* c. 18). The missionary reports were studied by Kant's philosophical predecessors such as G. W. Leibniz. In 1721, China shut down the mission and banned Christianity. After the expulsion of the priests, evolutionary ideas were associated with pagan defiance, and its proponents were ruthlessly silenced. That a non-Christian nation defied Christian nations had also political ramifications, which made support for Chinese ideas dangerous, as the pioneer of the German Enlightenment, Leibniz's student C. Wolff, learned when fleeing into exile in 1723.

When Kant published on the evolutionary hypothesis, he did so either obliquely, in a technical context in the 1740s, or anonymously to avoid censure. Even so, he could not avoid problems. *Living Forces* was rejected as a magisterial dissertation and Kant left school without a degree in 1748, only to return after the passing of the Pietist professor who had barred his advancement. *Universal Natural History* was published anonymously, but in 1756, the book was traced to him, which damaged his career, forced him to retract his views, and delayed his appointment to a professorship until 1770. At the same time, and despite this recanting, he did not refrain from dropping the odd remark either in class or in his publications.

### Appraisal

The anthropocentrism of Kant's animal ethics has drawn criticism by environmental ethicists and animal rights theorists alike. Both sentience (the capacity for experiencing pain) and subjectivity (the fact that animals are experiencing subjects of life) are reasonable grounds for according animals

moral standing and thus to conclude that direct duties are owed towards them. As philosophically deserved, these objections are, they are also historically misguided, because Kant had little choice to argue differently, since anthropocentrism was the politically enforced doctrine.

The evolutionary hypothesis, developed in Kant's pre-critical philosophy of nature, has not yet received the attention it deserves, largely because its context is metaphysics, which Kant in his mature critical thought subjects to skepticist deconstruction. But considering that his early speculations were prescient anticipations of eventual advances in cosmology, chemistry, and biology, they deserve another look.

New Orleans, LA, USA

## Definition

Immunity is the homeostatic balance of adequate biological defenses to fight infection, disease, or other unwanted biological invasion while having sufficient tolerance to avoid allergy and autoimmune diseases. In multicellular organisms immunity can be generally defined by the ability of a cell to react immunologically in the presence of an antigen, which provides protection to a particular disease by either a natural or acquired resistance.

## Introduction

Organisms (mammalian) are constantly exposed to pathogens that enter through either external surface (i.e., the skin) through wounds or the internal surfaces (i.e., epithelia) lining the respiratory and gastrointestinal (GI) tracts. The response to infectious challenge occurs in a coordinated two-step immune response. The first line of defense is called the innate immunity, which exists from birth before exposed to any pathogen or disease occurs. The innate response is a non-specific immediate and rapid response that is

activated by any pathogen it encounters. The innate immune response is also a critical step in the activation and regulation of the second line of the immune response, which is termed adaptive or acquired immunity. Acquired immunity is specific to one particular pathogen/disease, which creates an “immune memory” that allows the body to respond even faster and more effectively if a second infection with the same pathogen occurs. Normal innate and adaptive immune responses rely on a plethora of signals ranging from specific types of immune cells to numerous immunoregulatory molecules. Thus, both types of immunity are mediated partly by the actions of specific immune cells and partly by the actions of molecules secreted by various immune cells.

## The Innate Immune Response

The innate immune response comprises five main elements: (1) physical barriers, (2) pathogen recognition systems, (3) innate immune cells, (4) immunoregulatory molecules (as known as humoral innate immunity), and (5) the coordinated recruitment of other immune cells (i.e., adaptive immune cells). For a comprehensive review of innate immunity in vertebrates, see Riera Romo et al. (2016).

Innate immune responses usually begin with the physical barriers that prevent pathogens from entering the body. However, additional immune response mechanisms destroy pathogens after they enter or flush them out before they can establish infection. Barrier defenses do not respond to infectious insult, like other innate immune responses, but continuously work to protect against infectious insult. Barrier defenses are associated with the external surfaces of the body, where pathogens may enter the host. The primary barrier to the entrance of microorganisms into the body is the skin. The skin is covered with a layer of dead, keratinized epithelium that prevents or reduces bacterial growth; in addition these cells are continuously sloughed off from the skin; thus, bacteria and other pathogens are carried away from the body. The skin also produces sweat and

other skin secretions, which lower pH, contain toxic lipids, and physically wash microbes away. Salivary secretions in the mouth, as well as the acidic environment of the stomach, also act as a physical barrier for prevention of infection. Saliva is rich in an enzyme termed lysozyme, which destroys bacteria by digesting their cell walls, while the acid of the stomach is fatal to many pathogens. The mucus layer of the gastrointestinal tract, respiratory tract, reproductive tract, eyes, ears, and nose traps both microbes and debris and facilitates their removal. In the case of the upper respiratory tract, ciliated epithelial cells move contaminated mucus upward to the mouth, where it is then swallowed into the digestive tract, ending up in the acidic environment of the stomach.

Pattern recognition receptors (PRRs) are critical for the detection of invading pathogens and subsequent activation of the innate immune response. PRRs are primarily expressed by antigen-presenting cells such as macrophages and dendritic (see below for more information on macrophages and dendritic cells) but can also be expressed by the mucosal-associated epithelium. These cells express a variety of PRRs, such as the membrane-associated Toll-like receptors (TLRs) and cytoplasmic Nod-like receptors (NLRs) as well as retinoic acid-inducible gene like helicase receptors (RLRs). These PRRs recognize the conserved pathogen-associated molecular patterns (PAMPs) that are present on microbial proteins (i.e., nucleic acids, lipids, and carbohydrates). PAMP-containing molecules act as ligands that trigger PRR-dependent intracellular signaling pathways that ultimately induce the expression of pro-inflammatory and antimicrobial cytokines. Secretion of these cytokines at the site of an infection promotes the recruitment of neutrophils and natural killer (NK) cells (see below), which eliminate pathogenic microbes and infected cells.

Immunoregulatory molecules, such as antimicrobial peptides, reactive oxygen species, as well as the pH and lipid composition of the internal and external surfaces, prevent microbial growth and invasion. While all of the immunoregulatory molecules are necessary for a normal innate

immune response, several key immunoregulatory components of the innate immune response are cytokines, chemokines, interferons, complement, and acute-phase proteins. Cytokines are proteins made and released by innate immune cells, which have the ability to affect the behavior of other cells (e.g., activate other cells) and promote or stimulate cell–cell interactions. Cytokines released by immune cells serve several functions: (1) regulation of the production of new immune cells from precursor cells, (2) activation of lymphocytes and phagocytes, (3) coordinate the cell-mediated and adaptive immune responses, (4) promote and control the process of inflammation, and (5) direct killing of infected and/or diseased cells (Banyer et al. 2000). Important families of cytokines include the tumor necrosis factor family (e.g., TNF- $\alpha$ ) and the interleukins family (e.g., IL-8). Chemokines are produced and released in a very similar fashion to cytokines; however, their main function is to attract additional cells (e.g., monocytes and neutrophils) to the site of an infection. Interferons (IFNs) are proteins that are primarily involved in the immune response to viral infection. IFNs enhance resistance to viral replication and upregulate the cell-mediated immune response to viral infection. The complement system is comprised of a large number of plasma proteins, which results in a stepwise chain reaction that ultimately cover the surface of a pathogen in proteins when activated, a process termed *opsonization*, facilitation the recognized and ingested by professional phagocytes. Phagocytes are immune cells that engulf, ingest, and destroy pathogens in a process called phagocytosis. The complement system can be activated through three different biochemical pathways (i.e., the classical pathway, the alternative pathway, and the lectin pathway); see Walport (2001a, b) for a review of the complement system. Finally, acute-phase proteins (e.g., C-reactive protein, mannan-binding lectin, and pulmonary surfactants A and D) are produced early during the inflammatory response to infection. These proteins are important for the opsonization of pathogens, the clearance of monocytes that have ingested pathogens, and the initial activation of the complement cascade.

The cell-mediated arm of the innate immunity is orchestrated primarily by granulocytes, monocytes/macrophages, dendritic cells, and natural killer (NK) cells. Granulocytes (as known as polymorphonuclear leukocytes [PMNs]) are a type of white blood cells (i.e., leukocytes) that are characterized by large granules and oddly shaped nuclei with multiple lobes. PMNs represent approximately 60% of all circulating leukocytes (Yaseen et al. 2017), with neutrophils being the most abundant. Neutrophils not only serve as primary phagocytes; they excrete toxic substances from their granules, which can readily kill invading pathogens. Neutrophils produce a host of bacteria-killing molecules, such as myeloperoxidase, defensins, azurophil-derived bactericidal factors, bactericidal permeability-increasing protein, cationic proteins, gelatinase, and lactoferrin. Furthermore, neutrophils participate in the regulation of the local defense response by releasing cytokines and chemokines, which help to recruit and activate additional PMNs, as well as macrophages to the site of an injury or infection. Monocytes and macrophages are leukocytes with a single-lobed nucleus that also act as phagocytes, as opposed to the multilobed nucleus of the PMNs. Monocytes circulate in the blood until they are recruited to the site of pathogen incursion into the body. Once they are at the site of infection, they swell in size and develop into the mature cells (i.e., macrophages), which then enter the tissues to combat infection. Macrophages, as well as monocytes, eliminate pathogens by phagocytosis, following ingestion and destruction macrophages and monocytes exhibit pathogen-derived proteins and other molecules (i.e., antigens) on the cell surface. Display of pathogen-derived antigens is critical step for the activation of the adaptive immune response. Finally, monocytes and macrophages also produce certain cytokines that help regulate immune system activity. Dendritic cells also are mononuclear phagocytes derived from monocytes. Their main role is to capture, ingest, and process antigens in order to present them on their surface to cells of the adaptive immune response (i.e., to the T-lymphocytes, see below). Thus, dendritic cells play a crucial role in linking innate and adaptive

immune responses. Lastly, NK cells recognize cells that have low levels of a protein called class I major histocompatibility complex (MHC) on their surface and eliminate these cells. This reduced class I MHC expression can result from infection with certain types of viruses or cancer. The innate immune response provides the first line of defense against invading pathogens and plays a key role in the activation and regulation of the adaptive immunity.

## The Adaptive Immune Response

The innate immune response to a pathogen is followed by an adaptive or acquired immune response. The adaptive immune response is specific to one particular pathogen and is formed following the first exposure to one particular pathogen. Following exposure an immune memory is created; this allows the body to respond even faster and more effectively if a second infection with the same pathogen occurs. The activation of the adaptive immune response depends on the display of antigens from the invading pathogen on the surface of antigen-presenting cells (e.g., monocytes or dendritic cells) in a way that can be recognized by the cells of the adaptive immune response (i.e., T-lymphocytes [T-cells] and B-lymphocytes [B-cells]). For a review of the adaptive immune response, see Bonilla and Oettgen (2010).

T-cells are responsible for the cell-mediated arm of the adaptive immune response. T-cells are formed in the bone marrow and mature in the thymus, hence the name T-cells. T-cells circulate in the body in an inactive (naïve) state until they encounter a specific antigen. This encounter activates the T-cells, which then further differentiate into different subtypes. While our knowledge of the number and function of T-cell subtypes is continually expanding, two important subtypes of T-cells are helper T-cells and cytotoxic T-cells. Helper T-cells produce cytokines to stimulate the activity of other immune cells. Helper T-cells are further categorized into multiple subsets, with Th1, Th2, and Th17 helper T-cells being recognized as key T-helper cell subsets. For

further information on T-cell subsets, please see Raphael et al. (2015). Th1 cells produce IFN- $\gamma$  and mediate immunity against intracellular pathogens, while Th2 cells produce IL-4, IL-5, and IL-13 and promote humoral immunity and participate in the allergic response. Finally, Th17 cells produce IL-17, IL-21, and IL-22 and are implicated in host defense against fungal and bacterial pathogens, as well as autoimmunity. Helper T-cells are characterized by the presence of a molecule called CD4 on their surface. Cytotoxic T-cells recognize antigens on the surface of virus-infected or transplanted cells and destroy these cells; each cytotoxic T-cell recognizes only one specific antigen. Cytotoxic T-cells are characterized by the presence of a molecule called CD8 on their surface.

B-cells are responsible for the humoral arm of the adaptive immune response. They produce immune molecules called antibodies or immunoglobulins, which can either be display on the cell surface or secrete. Antibodies recognize and interact with antigens, and each B-cell produces antibodies that recognize only one specific antigen. The antigen–antibody interaction either through soluble antigen encounter or by antigen presentation through APCs leads to the activation of the B-cell. Activated B-cells multiply and mature fully in a series of developmental processes that are accompanied by changes in the class of immunoglobulin that the cell produces (i.e., immunoglobulin class switching). For further information on the different immunoglobulin classes and immunoglobulin class switching, please see Methot and Di Noia (2017). Immunoglobulins produced by each specific B-cell, and its daughter cells specifically recognize the same antigen. In most cases, the resulting B-cells develop into plasma cells, which secrete large amounts of the specific antibody into the blood or fluid between cells. These antibodies then will bind to any matching antigen molecules (i.e., those on an invading pathogen) in the blood or on other cells, thereby marking them for destruction. Other B-cells following antigen exposure develop into memory B-cells that will remain dormant in the body for years and can be activated rapidly if a second infection with the same pathogen occurs.

The activities of T-cells and B-cells are intricately intertwined through the actions of various cytokines for an effective immune response to any pathogen. The innate and the adaptive immune responses are critical for effective host defense to infectious challenges.

## Definition

The branch of biology that focuses on the immune system, as a whole or in part, to study their development, structure, and function, in particular how they recognize the self or non-self and provide defense responses for the animal body (Cooper and Alder 2006; Kindt et al. 2006). There are many branches of immunology, for example, neuroimmunology and psychoneuroimmunology are two subdisciplines that study the interaction between nervous and immune systems, which specifically targets the neurological health essential to normal animal cognition and behavior (Sattler 2017; Schaller et al. 2015).

## Introduction

Like humans, animals can be afflicted with infections when foreign agents enter their bodies or when their body parts malfunction. Animal immunology aims to improve the health and wellbeing of companion, production, and wild animals by studying structure and function of all the different molecules, cells, tissues, and organs that comprise an animal immune system (Cooper and Alder 2006; Kindt et al. 2006; Yuan et al. 2014). As a defense system, the two core functions of the

## Immunologic

- [Immunology](#)

immune system are recognizing and repelling foreign invaders such as microbes or eliminating malfunctioning cells and tissues such as cancer cells and tumors. All animals, essentially all organisms, have at least one form of defense known as innate or natural immunity. Higher vertebrates beginning with jawed fish and spanning to humans have evolved a complete immune system which includes adaptive immunity atop the innate immunity and has more specific immune organs (e.g., bone marrow, spleen, thymus, and lymph nodes), cells (e.g., T- and B-cells), and proteins (e.g., antibodies). Both innate and adaptive immunity are composed of humoral and cellular portions, in which each part consists of: (1) afferent arms for determining the self and non-self to recognize invaders and (2) efferent arms for inactivating and repelling invaders (Fig. 1) (Cooper and Alder 2006; Sang et al. 2011). Both innate and adaptive immunities work together and interact with other systems of the body to provide protection for both mental and physical health, which is essential for animal physiology underlying normal cognition and behavior (Sattler 2017; Schaller et al. 2015).

## Innate Immunity

Innate immunity is an in-born immune system and the first line of defense for the animal. Innate immunity responds immediately to an infection. Distinguishing features of innate immunity are that it is nonspecific and antigen-independent. Major components of innate immunity include: (1) physical barriers such as the skin and mucosa, (2) proteins and other immune mediators in the blood that cause immediate immune responses including inflammation and complement reaction, and (3) innate immune phagocytes including macrophages and neutrophils that are always ready to engage the antigens or whole microbes. Although less specific for recognizing individual antigens, the humoral and cellular arms of animal innate immunity do contain afferent components, namely pattern recognition receptors that detect the conserved features of pathogens that are not present in the uninfected host. This pattern-based detection provides an efficient and broad discrimination, thereby to sum up a variety of innate immune arsenal (efferent arms) to repel and kill the invaders. Innate immunity provides protection for all animal species and is the only immune

### Immunology,

**Fig. 1** Animal immune system. Schematic of animal immune system and its major parts in humoral and cellular formats. The afferent and efferent arms of each immune part are illustrated to highlight the immune function for determining and repelling foreign invaders. See text for detail. Abbreviation: *Ab* antibodies, *AMP* antimicrobial peptides, *miRNA* regulatory microRNA, *PRR* pattern recognition proteins, *ROS* reactive oxygen species

mechanism in animals other than jawed vertebrates. In addition to providing general protection to initially keep infection under control, innate immune responses also save time by activating adaptive immunity through the process of antigen presentation. Presenting antigenic peptides is a mechanism the cell uses to signal that it is infected and requires activation of adaptive immunity for antigen-specific defense (Cooper and Alder 2006; Kindt et al. 2006).

## Adaptive Immunity

Innate immunity provides a foundation for the adaptive immune system, which stands as a more complex and specific apex of animal immunity in higher vertebrates (Cooper and Alder 2006). Functionally, it serves as the final line of defense that will step in when innate immunity has failed to stop a pathogen from causing a disease and an infection has been established in the animal body. Adaptive immunity is the antigen-specific and antigen-dependent immune response that relies on recognition and processing of an antigen to activate a pathogen-targeting immunological response. After recognition of a specific antigen, the adaptive immune system adapts a clone selection process to propagate a plethora of antigen-targeting proteins (immunoglobulins) and immune cells (B- and T-cells). In addition to creating a directed response to the specific antigen, the adaptive immunity possesses the ability to create memory of every type of antigen it encounters which will allow for a faster, stronger, and more efficient response if the same antigen is encountered in the future (Cooper and Alder 2006; Kindt et al. 2006; Yuan et al. 2014).

To accomplish the above functions, adaptive immunity utilizes T and B cells. T and B cells originate from hematopoietic stem cells that are primarily located in the bone marrow. From the bone marrow, each of the two cell types has a unique path: T cells leave the bone marrow and mature in the thymus, after maturation B cells leave the bone marrow already expressing an antigen-binding receptor on the outside of the cytoplasmic membrane. T cells require antigen-presenting cells

(APC) to activate, while B cells are able to identify antigens directly for activation to become antibody-producing plasma cells (Kindt et al. 2006).

After activation, T cells will differentiate into two major groups: T helper cells and cytotoxic T cells. As the name suggests, the cytotoxic T cells are responsible for attacking and destroying cells that have been infected by a pathogen. Unlike the cytotoxic T cells, the T helper cells play an important role in directing the nature and intensity of immune responses such as to help B cells to secrete antibodies and cytotoxic cells to destroy ingested pathogens. Different subsets of T helper cells accomplish this task by directing other immune cells to function quickly and properly through production of a series of immune mediators (termed cytokines). As previously stated, the adaptive immunity is capable of creating memory. The host body will retain some of antigenically specific T cells and store them after an immune response so that these cells are available to differentiate quickly and mount a rapid response if the body is exposed to the same pathogen again.

In contrast to T cells, B cells serve the immune system by producing antibodies to neutralize antigens. After activation, B cells will either differentiate into antibody secreting plasma cells or memory cells. Again the memory cells will be stored and used if there is an antigenic re-exposure, while plasma B cells will die after the specific immune response has ended. Like the coordinative role between the innate and adaptive immunities in protection of animal body, the T cell B cell responses in adaptive immunity also work together; however, T cell responses are more effective for intracellular pathogens and cancers, whereas antibody response in humoral branch reacts more to extracellular antigens and microbes (Kindt et al., 2006).

## Conclusion

Innate immunity represents the rapid and first response by the immune system that occurs within hours of the detected presence of foreign agents. It is an in-born and nonspecific response used to fight against infections. This response is mediated by humoral mediators and immune cells. In

addition to general innate immunity existing in all animals, adaptive immunity in high vertebrates develops a specific response to target and eliminate pathogenic threats escaping from innate immune protection. Adaptive immunity depends on the communication between APCs, T cells, and B cells to not only mount an immunological response but also to develop memory. Development of memory provides the system with the ability to absorb and record involvements with previously encountered pathogens, which allows for a more rapid response in the event of future exposures. It is the combination of the specific adaptive immunity and the broad but immediate innate immunity that offers a complete defense for the animal when functioning properly. Remarkably, current views state the role of physiological regulation of immune system in maintenance of animal homeostasis even in healthy animals, which integrates into the wholesomeness of animal health physically and mentally (Sattler 2017).

[Unsolvable task paradigm](#)

## Definition

Experimental procedure eliciting an immediate and unanticipated *expectancy violation*.

## Introduction

Research in comparative cognition and ethology has grown exponentially in the last few decades, and with this growth, we have seen a diversity of paradigms for studying the cognitive abilities of animals. The impossible task paradigm is one of these developments, and its use provides insight

into the decision-making processes of animals, particularly in the realm of expectancy violation.

## Methods and aims of the impossible task paradigm

The impossible task paradigm consists of a number of solvable trials in which the experimental subject solves an easy task to obtain a reward (e.g., food or toy) by manipulating an apparatus, followed by an unsolvable trial in which the reward becomes unreachable. This paradigm is a useful tool for assessing capacities for requesting help and the decision-making process in different species. In fact, it is a widely used procedure used by behavioral scientists who study canine cognition, and particularly how canines communicate with humans while attempting to solve problems.

The impossible task resembles the problem-solving paradigm. However, in the latter the animal tries to solve a task not knowing if it is solvable or not, whereas in the impossible task, the experimental subject initially learns that the task is easy to solve, but afterward the same task becomes unsolvable. The problem-solving task could also become impossible when the animal is not able to solve the task, but the focal element (i.e., violation of expectation) is missing.

The impossible task paradigm can be applied using different devices. Miklósi et al. (2003) used bin-opening and rope-pulling tests in which animals learn to obtain food by opening a bin or pulling on a rope from a cage during training trials. Afterward the animals are exposed to the impossible trial, in which the bin was closed mechanically or a hidden end of the rope was fastened to the cage, making the task unsolvable. A different device was employed by Marshall-Pescini et al. (2009): for the solvable trials, the apparatus comprised a wooden platform upon which food was placed and covered with an upside down plastic container that could be either moved off the platform or overturned to obtain the food. During the unsolvable trial, the container was screwed to the wooden platform and

food became inaccessible. Horn et al. (2012) constructed an impossible task with an apparatus consisting of two wooden discs attached in two-tiered fashion. The lower disc held six round food containers that could be accessed by rotating the upper disc to align it with a hole that allowed the subject to retrieve the food. The apparatus also included a locking mechanism that, when activated, prevented rotation of the upper disc. In Persson et al. (2015), the apparatus consisted of three plates on a solid foundation covered by three transparent lids. The subjects could reach the food inside the plate by sliding a lid to the side. In their experimental setup, one of the three lids was secured, making it impossible to open. In all cited studies, at least one person is present during the test phase (an experimenter or a person who is familiar to the animal), whom remains inactive, leaving the subject free to choose whether to interact with him or her.

Research using the impossible task paradigm with canids focuses on various behaviors that indicate expectancy violation. Generally the most commonly observed behaviors during the unsolvable phase of the tests could be grouped into two broad categories: apparatus-directed behaviors and human-directed behaviors. The former category includes all types of interaction or manipulation of the apparatus (e.g., rubbing, smelling, touching) and head and eye gaze orientation toward it. The human-directed behaviors are categorized as either active (e.g., jumping on the person, pawing to call attention) or passive (e.g., proximity, maintaining close physical contact). Human-directed behaviors might also include gaze or looking back behaviors (e.g., from a stationary position, the subject turns/lifts its head toward human faces, without approaching). In order to clarify whether the animal's orientation toward a human may be a request for help, Smith and Litchfield (2013) stressed the importance of using precise terminology and to minimize ambiguous definitions. For example, the behavior of gaze and looking back may be interpreted differently: the first behavior refers to those experimental contexts in which it is possible to observe the direction of the animal's

eyes, while in the second case, it is possible only to deduce the orientation of animal's head without seeing its eyes. The gaze alternation between human and apparatus is considered a communication tool and is often used in the analysis of the behavior during the unsolvable task. Other behaviors that can be observed during an unsolvable task are vocalizations (e.g., bark, howl) and stress behaviors (e.g., shaking, yawning, panting, lip-licking).

Results from studies using the impossible task paradigm have demonstrated that specific behaviors, such as physical contact or gaze toward the human, can depend on genetic factors (Persson et al. 2015), likely due to the process of domestication (Miklósi et al. 2003). On the other hand, some investigators have emphasized the role of ontogenesis, showing that the tendency to gaze at humans was positively correlated with age (Passalacqua et al. 2011) and can depend on the type of training that dog received (D'Aniello et al. 2015, Scandurra et al. 2015) or by the living conditions, with kennel dogs gazing less to humans than pet dogs (D'Aniello and Scandurra 2016). Comparative studies suggest that in toddlers and dogs gaze alternation is both an intentional and referential communicative act (Marshall-Pescini et al. 2013).

## Imprinting

Peter H. Klopfer

Department of Biology, Duke University,  
Durham, NS, USA

Imprinting (or, Praegung, in German) has been defined as the development of a stable preference for an object or pattern as a consequence of a relatively brief exposure to said object during a limited and specific developmental stage, referred to as the critical period. It is also distinguished by the absence of extrinsic reinforcement (Klopfer). In the early part of the twentieth century, it was described by the German ornithologist, Heinroth,

who noted that newly hatched waterfowl, who normally follow their parent when they first leave their nest, would instead follow him if he had substituted himself at the time the young were ready to leave and would thereafter ignore their parent, preferring to follow him. Some years later, in the 1930s, Lorenz popularized the topic with films showing goslings that he had hatched following him around his lawn or while swimming in his pond, rather than adult geese. As the animals reached maturity, their sexual behavior was also preferentially directed towards him. Following the end of the war, in the early 1950s, Lorenz and his students focused much of the early work at his field station in Seewiesen, Bavaria, on imprinting and its consequences, and it was they who were largely responsible for bringing it to the attention of students of behavior and psychology in other countries.

Allusions to the process of attachments being established as a result of brief exposures early in life date back much further than the work of Heinroth and Lorenz, however. The first explicit references appear in a paper by a young tutor in England, Spalding, who, in 1872 reported experiments with newly hatched chickens that were comparable to those performed decades later by Lorenz and his students. That study, however, did not attract much attention until rediscovered in the 1950s by Spurway. And, in 1880, William James alluded to the phenomenon in his *Principles of Psychology*. Studies of imprinting, however, did not truly blossom outside of Seewiesen and the Lorenz lab, until the early 1950s, when the topic was highlighted by Thorpe in his, at the time monumental, treatise, *Learning and Instinct in Animals*.

As imprinting became an increasingly interesting topic for students of behavior, a variety of different questions emerged:

1. How universal a process is it? The “following response,” which leads to imprinting in geese, obviously cannot occur in altricial birds, so is imprinting limited to precocial species? Do similar processes occur in animals other than birds? In mammals? In insects? In Heinroth

and Lorenz’s examples, the imprinting is onto a parent figure, which subsequently becomes the object of sexual attachment. However, entomologists had long known that the plant species on which some butterflies deposit their eggs determines the preference for the oviposition site of the next generation. Is this a comparable process? In goats, Collias had shown that a newly born kid would only be accepted by its mother if she had been permitted contact with it during the first few minutes or so directly after its birth. Was this also an instance of imprinting?

2. What sensory modalities are involved? In the case of ducks and geese, it is obviously vision, but what happens when the species nests inside tree hollows or underground, where the “following response” is limited and the parent may not be visible? Gottlieb and his associates found the calls of the female duck to be significant and that imprinting to auditory signals could occur. In the case of butterflies, and insects in general, olfactory imprinting seems to be involved, as well as in mother-infant bonding in mammals.
3. There is a critical period during which and only during which imprinting can occur. What factors determine its onset and end? In the case of newly hatched goslings, it is obvious that they are unable to locomote freely until they are about 18–20 or so hours out of the shell and their down has dried. Thus, that is the earliest age at which imprinting can occur. By about 30 h post-hatching, it is difficult to elicit the “following response” and imprinting. Why is that? In the case of the goats studied by Collias, it appears that hormonal influences, specifically the breakdown of oxytocin, ends the mother’s interest in her offspring. What other factors could be involved?
4. The existence of the so-called critical period, the restricted time during which and only during which imprinting can occur, has led to a metaphoric comparison to sealing wax which can receive the imprint of a seal only during the brief period that it is still soft. How malleable is that interval? Sealing wax, if kept warm, can

retain the ability to accept an imprint. Can the critical period be extended?

5. What are the later consequences of imprinting? Lorenz claimed that in his ducks and geese the sexual partners at maturity were determined at the time the “following response” was first elicited. His geese would continue to follow their imprinted “parent,” which could be Lorenz himself, until they were fully fledged, by which time the “following response” would have waned. But, later, once sexual maturity was attained, it would be that imprinted object that would be the preferred target of attention. If imprinting was onto oviposition sites, as in insects, or, in mammals, to particular foods whose odors were present in the amniotic fluids of their mothers, what consequences might follow?
6. Is imprinting an ancient, conserved trait or an adaptation that has appeared independently in different lineages? Genomic studies related to imprinting have yet to be conducted but would do much to clarify many of the questions surrounding this unusual form of learning.
7. Imprinting is said to differ from other forms of learning due to both the existence of a critical period and the absence of extrinsic reinforcers. Are there not intermediate conditions, or is imprinting truly a unique form of learning?

### Definition

In a heterozygote, the inbreeding raises the possibility of homozygosity of injurious recessive alleles in an innate population. In another hand, one of the consequences of inbreeding is a loss in vigor (i.e., not as much of productive vegetatively and reproductively) which usually accompanies a huge swell in homozygosity known as inbreeding depression.

### Introduction

Inbreeding depression would possibly or may not be caused by inbreeding because it is the reduction within the fitness of the offspring created through sexual reproduction either through the breeding or mating system of individuals which are strongly connected genetically. This method ends up in homozygosity. The inbreeding depression is especially caused by inbreeding that may be a universal development that depends on selection, past mutation, and genetic drift.

This development happens altogether in wild animals, in humans, and in addition in plant populations, representing those genetic variations in fitness traits exist each inside and among the normal populations. Inbreeding depression plays a significant role within the crop breeding and within the evolution of outcrossing coupling systems.

For a long time, man has accepted inbreeding depression. In several species marriage between

closely connected ancestries is prohibited. Hindu society may present an acute example, where marriage between individuals connected by ancestry is prohibited.

### Inbreeding Depression in Plants

Onion, carrot, maize, sunflower, etc. are few examples of plants created by inbreeding depression either by the self-pollination or cross-pollination method. This development is discovered in many different plant species that are a unit any sorted supported the subsequent four classes.

- **High inbreeding depression:** An oversized proportion of plants created by the self-pollination ends up in severe depression and exhibits a lethal result. It's terribly laborious to keep up the line once, after three to four generations due to the loss of vigor and fertility. These are principally seen within the alfalfa of a family *Leguminosae* and in carrots.
- **Moderate inbreeding depression:** At the side of the lethal effects, sublethal effects are seen in the offspring's made by the self-pollination. There's a substantial decrease in the fertility, as some lines formed are very poor and are lost. *Maize*, *Pennisetum americanum*, and *Sorghum* could be a few samples of plants showing moderate inbreeding depression.
- **Low inbreeding depression:** A minor proportion of the plants exhibit lethal characteristics. The loss of vigor and fertility is lesser, and due to the poor fertility, a line can't be maintained which ends in a reduction in yield due to inbreeding being low or absent. Onion, squash, pumpkin, and sunflower are a few examples of plants showing low inbreeding depression.
- **No inbreeding depression:** This development is especially seen within the self-pollinated species as they do not show any inbreeding depression, although they are doing to show heterosis. It's as a result of they reproduce each by self-pollination with developed homozygous balance and cross-pollination by heterozygous balance.

## Inbreeding Depression in Animal Breeding (*Vipera berus*)

*Vipera berus* is frequently referred to as European adder or European viper. It is a venomous snake that's very widespread in Western Europe and East Asia.

A set of 40 *Vipera berus* experienced inbreeding depression, and a bigger range of distorted and stillborn offspring were made within the isolated population than within the larger population. Once when introducing the *Vipera berus* from different inhabitants into the isolated population, they manufacture by recovering a developed segment of viable offspring.

The reason behind the recovery is that a species of *Vipera berus* with a one recessive harmful allele will be healthier and can reduce the carrier's fitness. Therefore, less copy finishes up in the next generation.

At last, the inbreeding depression is generally seen only in the minor population rather than the larger population. For the reason that is in the minor population, when the families buddy, there are possibilities that a progeny inheriting two copies of the equal recessive harmful allele will undergo the significances of expressing the harmful allele.

In humans, this development is incredibly rare. It's especially found in the case where the marriages between closely connected ancestries are performed.

## Mode of Action

Ayroles et al. (2009) also assessed the mode of gene action associated with inbreeding depression. They generated a collection of three "outbred" lines by crossing the three homozygous high inbreeding depression lines every alternative and contrasting gene expression between these parental inbred lines and their F1 hybrid offspring showing heterosis for the third chromosome. Results indicated that the expression of roughly 75% of all differentially expressed genes related to inbreeding depression were additive or dominant and concerning 25% of all of those genes

expressed patterns of overdominance. This was surprising, on condition that overdominance for expression is assumed to be rare (Gibson et al. 2004). Through an experiment, comparable studies by Gibson et al. (2004) and Hughes et al. (2006) found fewer genes showing vital patterns of overdominance (>5% of genes) in *Drosophila melanogaster*. Moreover, it's necessary to denote that only a miniscule fraction of the genome has been sampled in the majority of studies on inbreeding depression, thus far creating any general mechanistic interpretation premature (Ayroles et al. 2009).

## Genetic Origin of Inbreeding Depression

Following the find of Mendelian genetics, two main hypotheses were developed to account for the existence of inbreeding depression and heterosis (gains in fitness following outbreeding; reviewed in Wright 1977; Charlesworth and Charlesworth 1999). The overdominance hypothesis (East 1908) argues that state confers properties that are superior to either homozygote. The loss of heterozygosity through inbreeding can so decrease the mean of traits related to fitness and lead to inbreeding depression (Lynch and Walsh 1998). The dominance hypothesis (Davenport 1908), on the opposite hand, argues that the majority mutations are neutral or injurious and usually recessive (MacKay 2001). Increasing the proportion of homozygotes through inbreeding will raise the probability of unmasking these deleterious alleles (Charlesworth and Charlesworth 1999), leading to inbreeding depression (Keller and Waller 2002). Which of the two hypotheses explains most of the decline in fitness related to inbreeding remains being debated (Ritland 1996; Käärkkäinen et al. 1999; Roff 2002). Though proof exists to support each models (Hughes 1995, Li et al. 2001, Carr and Dudash 2003), the dominance hypothesis seems to be favored on the idea of obtainable empirical knowledge and on theoretical grounds (Charlesworth and Charlesworth 1999). Others have suggested that inbreeding depression can also be explained, a minimum of partially, by synergistic or epistatic

interactions among genes (Templeton and Read 1994; Charlesworth 1998).

## Molecular Approaches to Inbreeding Depression

Although inbreeding depression has been a central theme in biological research for quite a century, very little is understood regarding its underlying molecular basis. For example, we've got no plan what the number of loci is also concerned in inflicting inbreeding depression of fitness and its parts. The amount may be tens, hundreds, or even thousands (Frankham et al. 2002). The genes or gene pathways related to inbreeding depression are also unknown.

For some decades, molecular genetics approaches to inbreeding depression have relied predominantly on the use of neutral markers (i.e., RFLPs or microsatellite markers) for assessing levels of genetic variation. Using RFLPs, one can detect genetic variation among individuals by cutting every individual's DNA with a selected restriction enzyme, subjecting those DNAs to electrophoresis in agarose gels, and transferring them to charged nylon membranes by use of Southern blots. Nylon membranes are then hybridized to radioactively or biotin-labeled clones (i.e., specific pieces of DNA). Useful clones will be those showing polymorphism between two or more individuals. Once identified, microsatellites are amplified using the polymerase chain reaction and sized using gel electrophoresis or an automated sequencer. Microsatellites owe their variability to associate redoubled rate of mutation compared with other neutral regions of the DNA. High rates of mutation are often explained predominantly by slippage throughout DNA replication. Each of these techniques allows the detection of homozygous and heterozygous loci for each DNA sample. For example, from a conservation perspective, populations of varying size could be compared for levels of genetic variability. Small populations with low levels of variation very likely have the highest risk of inbreeding depression and have a high risk of experiencing continuing losses of genetic

variation resulting from perennial bottlenecks and genetic drift (Wayne and Morin 2004).

More recently, neutral markers are used for mapping quantitative trait loci in an attempt to know the molecular basis of inbreeding depression (Carr and Dudash 2003).

With the generation of huge amounts of DNA sequence data and therefore the advent of DNA (cDNA) microarrays (Schena et al. 1995), in the case of inbreeding depression, changes in the multigene patterns of expression will give clues regarding the amount of genes concerned, their modes of action, and the biochemical pathways leading to such effects. This newly based study of gene-expression patterns is often named as "functional genomics" (Amundson 2008).

## Conclusion

It is apprehensible that inbreeding depression is related to a large number of gene transcripts, primarily genes related to metabolism, stress, and defense. Genetic drift alone is an unlikely clarification for these patterns given the moderately large amount of replicates within and across many studies that have repeatedly uncovered identical genes and gene pathways. Whether there are a large number of genes of small effect or a few key genes that have an effect on the expression of many different genes (i.e., epistatic effects) is unclear. However, when the proportion of genes differentially expressed across inbred lines by chromosomal location were assessed, roughly simple fraction of the differentially expressed genes were on the third chromosome, and roughly common fraction of the differentially expressed genes were on the second, fourth, and X chromosomes. Since these lines were variable just for the third chromosome, variation found on the second, fourth, and X chromosomes had to originate from genes located on the third chromosome.

## Introduction: From Folk Psychology to Experimental Research

Helen saw a picture of an attractive man in an online dating page and is happy that he accepted to meet her in a coffee house. As he arrives, Helen feels disappointed because the picture posted online does not reflect the current looks of the person. Is Helen's disappointment caused by his current looks or by the expectation she developed after seeing his picture? Tom used to like sweets, but after being treated for surgery-related pain, he developed an opioid addiction. Now, whenever he is having ice cream all he can think of is going home and taking a few pills. Has Tom lost his sweet tooth or does anticipating an opioid high make him lose his appetite for that ice cream he used to like so much? These two examples illustrate the fact that in addition to its absolute value, an incentive's value may depend on how it compares to other incentives that were expected to occur (as it happened to Helen) or are expected to occur in the near future (as in Tom's situation). *Incentive relativity* refers to a distortion in the absolute value of an incentive when the

incentive occurs in the presence of expectancies of different value.

Incentive relativity is connected to a variety of psychological processes, including expectancy, motivation, emotion, and memory. To illustrate its relevance, imagine living surrounded by people who can only evaluate incentives by their absolute value. In such a society, the same outcome would have the same emotional impact regardless of prior experience. Two people losing a thousand dollars in a Las Vegas casino would have a similar emotional response whether one of them is a successful lawyer in a Manhattan firm and the other an unemployed worker. Incentive relativity may allow the lawyer to remember the casino experience as exciting, while the jobless worker would feel emotionally devastated. Similarly, a wave of public protest against government decisions can be described in terms of “relative deprivation,” that is, the experience of being deprived of something a person feels entitled to receive. Incentive relativity can also interfere with our ability to empathize with friends when we see their problem from our perspective, rather than theirs, or lead us to underestimate or overestimate our resources and abilities because we have inaccurate expectations of what we can achieve. The pervasive influence of incentive relativity in daily life makes it relevant to understand the conditions, mechanisms, and neural machinery that make such comparisons possible.

## Brief Historical and Terminological Background

The role of incentives in animal learning has been a major topic of interest since the early twentieth century (Flaherty 1996). Initially, the interest was in comparing the effectiveness of rewards that differed either qualitatively or quantitatively in their capacity to change behavior. Incentives were conceptualized as the goal that aroused, directed, and brought to a conclusion the behavior of an animal. A major breakthrough came when Tolman (1932) demonstrated that animals form expectations of future events, rather than responding via stimulus-response associations,

as proposed by Thorndike (1911). Some years earlier, O. L. Tinklepaugh, a graduate student in Tolman’s lab, reported that monkeys accepted a piece of lettuce under a cup after seeing the experimenter depositing the lettuce there, but they refused to eat the lettuce after seeing the experimenter placing a piece of banana, their favorite incentive, under the cup and even displayed aggressive responses directed at the experimenter. Similar results were reported in analogous experiments with rats exposed to a downshift from a more preferred food to a less preferred, but acceptable food, or from a larger amount of food to a smaller amount of food. In these experiments, the instrumental performance of downshifted animals rapidly deteriorated in comparison to that of animals always receiving sunflower seeds – the unshifted control. *Incentive relativity* refers to the fact that the value of an available reward is in some cases weighed against the value of expected rewards.

Incentive relativity effects were not compatible with then dominant learning theories (e.g., Thorndike 1911). As a result, this research had a long-lasting influence on the development of learning theory that reaches to our day, about a hundred years later. There are several procedures designed to study incentive relativity and the terminology requires clarification (see Table 1). The term *contrast* refers to an apparent exaggeration of reward differences brought about in animals experiencing two rewards in a particular situation (Flaherty 1996). Contrast implies a comparison of incentives in which one is always present and the other may be present, remembered, or anticipated. In successive contrast effects, the organism is exposed to a transition in incentive value from higher to lower (*successive negative contrast*, SNC) or from lower to higher (*successive positive contrast*, SPC). *Incentive* has been used traditionally to refer to a reward expectancy, but here it is used simply as a synonym of reward and appetitive reinforcer. *Expectancy*, in turn, refers to a prediction of the impending presentation of an incentive with specific properties. Typical incentives include sucrose, saccharin, food pellets, natural foods, drugs, and brain stimulation. The term *successive* refers to the fact that there is usually a

single transition in reward that occurs across sessions. Successive contrasts have been studied in instrumental (iSNC, iSPC) and consummatory (cSNC, cSPC) situations. *Instrumental responses* are assessed before the animal comes into direct contact with the incentive and are thus anticipatory. Typical measures involve errors, latency, speed, and response frequency. *Consummatory responses* involve interaction with the incentive, usually in terms of consumption. Typical measures include licking frequency, cumulative time in contact with the reward, and fluid intake. In a cSNC experiment, the effects of reward downshifts are assessed in terms of consummatory behavior, typically after a downshift in sucrose concentration (e.g., a downshift from 32% to 4% sucrose). Such a downshift leads to a transient suppression of consummatory behavior relative to that of an unshifted 4% sucrose control. This model is playing a key role in our understanding

of incentive relativity processes and is covered below in detail.

In addition to successive contrast, reward relativity has also been studied in simultaneous and anticipatory contrast procedures (Flaherty 1996). In *simultaneous contrast* situations, trials with small or large rewards, each signaled by a discriminative stimulus, are mixed randomly within a session and the performance in either of these trials is compared to unshifted small and unshifted large controls, respectively. The key outcome in simultaneous contrast experiments is that animals receiving both reward magnitudes exhibit lower performance for the small reward than animals that only receive the small reward (i.e., an instrumental simultaneous negative contrast effect). Negative simultaneous contrast is also obtained in consummatory procedures. For example, animals exposed to repeated access to two sucrose solutions (32% and 4%) within the same session consumed more of the 32% and less of the 4% than unshifted controls exposed just to 32% sucrose or just to 4% sucrose, respectively.

In a similar procedure, often termed *behavioral contrast*, two or three reward schedules differing in reward magnitude or frequency alternate within a session, each with its own discriminative stimulus. Performing an operant response (lever press, nose poke) in each component is usually the key response measure. In this case, the rate of responding maintained by a constant schedule during one stimulus is increased by reductions in the reinforcement rate during an alternative component of the schedule (Flaherty 1996).

Incentive relativity may also influence behavior in an anticipatory manner (see below). Rats exposed to two palatable solutions in sequence may suppress intake of the first solution (e.g., 0.15% saccharin, 4% sucrose) if the second solution is preferred (e.g., 32% sucrose).

In the rest of this entry, we will focus on two incentive relativity paradigms extensively analyzed from a psychobiological perspective: successive and anticipatory contrast, especially as they are studied in consummatory situations involving reward downshifts. References to other procedures may be brought to bear on specific issues. This concentration reflects contemporary interests in

these forms of contrast, in their similarities and differences, and in their usefulness as models for the study of psychological pain, conflict, and addictive behavior.

## Consummatory Successive Negative Contrast (cSNC)

Basic behavioral phenomena associated to cSNC have been extensively reviewed in readily available articles (Flaherty 1996; Ortega et al. 2017; Papini et al. 2015; Torres and Papini 2016). Here we will center on four factors: detection, motivation, emotion, and memory.

### Detection

Rats trained in a runway to collect various numbers of food pellets and then downshifted to one pellet exhibit an iSNC effect directly proportional to the size of the disparity between pre- and postshift magnitudes. What is the rule regulating the detection of such reward disparity? To uncover the detection rule, Papini and Pellegrini (2006) gave three groups of rats access to either 16%, 24%, or 32% sucrose in four trials per day. Every other day, the second or third trial in the session involved an occasional downshift. For each group, six concentrations were used in downshift trials chosen so as to generate the same postshift/preshift ratios (8-to-1). When the cumulative time in contact with the sipper tube for each group was plotted against the absolute postshift concentration or against the difference between the preshift minus postshift concentrations, the functions for these three groups diverged significantly. However, when consummatory behavior was plotted against the ratio of postshift/preshift concentrations, the three functions overlapped and all differences disappeared (see Fig. 1). Therefore, consummatory behavior during a downshift episode was determined by a *ratio invariance rule* akin to Weber's law for sensory comparisons. A second experiment using the conventional cSNC preparation confirmed these results, except when the postshift solutions were either too high (above 16% sucrose) or too low (below 2% sucrose). This ratio invariance rule also

**Incentive Relativity, Fig. 1** Groups exposed to 32%, 24%, or 16% sucrose (called “training solutions”) were occasionally downshifted to a series of sucrose concentrations between 1.5% and 24% sucrose (called “test solutions”). When the results were plotted as a function of the test solution *top*) or the training minus test difference (*middle*), there were significant differences between groups receiving reward downshifts from different training solution to the same test solution (e.g., 16-to-8% vs. 32-to-

8% sucrose). However, when the same results were plotted as a function of the test/training ratio, the functions overlapped and differences were not observed. Such overlap suggests that the degree of consummatory suppression during a downshift depends on the proportion between the two solutions, rather than their absolute values or their difference. Results from Papini and Pellegrini (*Learning and Motivation*, 2006, Fig. 2, reproduced with permission from Elsevier)

applies iSNC (Pellegrini and Papini 2007). Rats reinforced for running with either 32 or 16 pellets exhibited overlapping postshift performance after a downshift to four or two pellets, respectively. Interestingly, ratio invariance was strong far from the goal, but it was less clearly observed close to the goal compartment of the runway. Using a rat autoshaping preparation with sucrose solutions as the reward, Pellegrini and Papini (2007) replicated the absence of iSNC when sucrose solutions are used as the reinforcer (see Flaherty 1996), but still observed ratio invariance after reward downshifts.

Little is known about the neural basis of ratio invariance in the SNC situation, but the hypothesis that opioid receptors are involved has received some support (Ortega et al. 2017). In one experiment, independent groups were exposed to the following downshifts: 32-to-6% and 16-to-3% sucrose (ratio: 0.19), and 32-to-12% and 16-to-6% sucrose (ratio: 0.38). Treatment with naloxone, a nonselective opioid receptor antagonist, before the first downshift session shifted the behavioral response from a ratio-based to a difference-based rule: the suppression was maximal for animals exposed to the 32-to-6% sucrose downshift, which experienced a 26% drop in sucrose concentration, and minimal for animals exposed to the 16-to-6% sucrose downshift, which were subject to a 10% reduction in sucrose concentration. Antagonist drugs, like naloxone, do not generate action potentials; rather, they prevent endogenous opioids to act on the receptor. Therefore, this naloxone effect on cSNC implies that endogenous opioids must be released during an experience of reward devaluation. Although the brain site of this effect is not known, one prime candidate is the amygdala (see below).

### Motivation

Behavior in a situation involving reward shifts also depends on internal factors. A major internal factor in situations involving access to food is the extent of food deprivation (Flaherty 1996). In the cSNC situation, for example, nondeprived animals usually drink less 32% sucrose than 4% sucrose, a fact that complicates the analysis of postshift performance. Nondeprived animals also

respond differently to reward downshift relative to deprived animals, showing an extended cSNC effect. This extended cSNC effect may be related to a reduced need for calories in nondeprived rats, provided that a downshift from 32% sucrose to 0.15% saccharin, which lacks caloric content, also leads to an extended cSNC effect. Similarly, inducing a need for sugar with exogenous insulin eliminates the cSNC effect based on sucrose intake.

The value of a reward also seems to depend on the internal state of the animal at the time the reward is consumed. Cuenya et al. (2015) fed animals with food pellets either before or after a session involving access to sucrose solutions during ten preshift sessions in a cSNC situation. Presession feeding should have devalued the sucrose solution, whereas postsession feeding should have had at best a modest effect on sucrose consumption. All animals experienced presession feeding before each postshift session, when the concentration of the sucrose solution was devalued from 32% to 4%. Whereas animals that had experienced postsession feeding during preshift sessions exhibited a cSNC effect, those that had experienced presession feeding failed to show evidence of a cSNC effect. The implication is that presession feeding had devalued the 32% sucrose such that a downshift to 4% sucrose was not experienced as particularly significant. Overall, these data suggest that the value of the 32% sucrose reward depends not only on its absolute properties but also on the internal state of the animal at the time of its consumption.

### Emotion

Since the early demonstrations of incentive relativity, interpretations have favored either emotional or cognitive mechanisms to account for the response to reward downshift. There is no question that reward downshift provokes an increase in search behaviors that seem appropriate to either find the missing resource or switch to another source of reward (Flaherty 1996). For example, when trained in a small conditioning box, rats subjected to a 32-to-4% sucrose downshift exhibit increased activity and rearing behavior and when trained in a radial arm maze,

exploratory behavior in nonbaited arms increases during postshift trials. While emotional and cognitive changes are not necessarily incompatible, there is evidence that search behavior is not necessary for a cSNC effect to occur. Lopez Seal et al. (2013) trained rats to voluntarily enter a tube to collect sucrose solutions. Once inside, animals were unable to turn around but could either lick or not at the sipper tube dispensing the solution. Under conditions that prevented full-blown search behavior, rats still exhibited a cSNC effect. The implication is that incentive relativity is accompanied by a negative emotional response that inhibits or redirects approach to the site previously associated with a highly valuable reward.

In fact, unexpected reward omissions and devaluations are known to induce changes associated with negative emotion, including distress vocalizations, odor emissions, stress hormones, and aggressive behaviors, among others (see Papini and Dudley 1997). An additional aspect that evokes a clear connection with emotion is the extensive overlapping between incentive relativity and physical pain, leading to the notion that reward loss and devaluation can be conceptualized as psychological pain (Papini et al. 2015). In accordance with this view, opioid and cannabinoid agonists reduce the cSNC effect, whereas opioid antagonists enhance it (Ortega et al. 2017). Another source of evidence involves the bidirectional interacting relationships between reward relativity and sensitivity to peripheral pain. Animals exposed to a 32-to-4% sucrose devaluation exhibit reduced sensitivity to physical pain in a variety of situations. By contrast, exposure to peripheral pain and restraint stress enhance the size of the cSNC effect (Papini et al. 2015).

The attenuating effect on cSNC of anxiolytics provides a third source of evidence that reward relativity is accompanied by negative emotion. Flaherty (1996) reviews extensive evidence that benzodiazepine anxiolytics (e.g., chlordiazepoxide, midazolam) and ethanol reduce the cSNC effect during the second downshift session but have no measurable effect during the first downshift session. If the typical 5-min session is substantially lengthened or several cycles of reward devaluation are administered, then the cSNC

effect is reduced by anxiolytics during the initial downshift session. Thus, some experience with reward devaluation is needed before anxiolytics can act, a fact that prompted Flaherty (1996) to propose a multistage model of cSNC. According to this model, negative emotion arises when the animal enters into an approach-avoidance conflict stage, with the anxiolytics then reducing avoidance and ameliorating the cSNC effect.

Compelling evidence that reward relativity induces negative emotion comes from a phenomenon traditionally known as escape from frustration. In this situation, rats are confined to a location where they have access to a large reward for several sessions. On one session, they encounter no reward (extinction) and then, after a few seconds, a door that had been closed is opened. These animals exit the extinction location faster than controls that had never received a reward in that box. This effect is eliminated by opioid blockade with naloxone (Papini et al. 2015).

Extensive research with inbred Roman high- (RHA-I) and low- (RLA-I) avoidance strains also provides evidence consistent with a relationship between reward downshift and negative emotion (Torres and Sabariego 2014). RLA-I rats, which exhibit high anxiety levels in a variety of situations, also show a longer cSNC, a greater iSNC, and a faster extinction after reward omission. Interestingly, RLA-I increased ethanol consumption and preference immediately after experiencing appetitive extinction, a result interpreted in terms of emotional self-medication. Outbred Wistar rats also showed increased consumption and preference for ethanol and the anxiolytic chlordiazepoxide immediately after experiencing a 32-to-4% sucrose devaluation (Torres and Papini 2016).

Finally, evidence suggesting a link between reward relativity and negative emotion comes from the effects of neural manipulations on cSNC. For example, transient lidocaine inactivation of the centromedial amygdala impairs the cSNC effect, increased activity in the open field, and had no effect on ANC (Kawasaki et al. 2015). Several studies further show that corticomedial amygdala lesions, diazepam infusions into the central amygdala, lesions of the insular cortex,

lesions of the ventrolateral orbital cortex, and lesions of the anterior cingulate cortex modulate the cSNC effect (Ortega et al. 2017; Papini et al. 2015).

### Memory

Adjustment to the cSNC situation implicates several memory processes (Papini 2003). First, the animal learns to expect access to 32% sucrose during the initial ten sessions. This *expectancy memory* is required to account for the rejection of the 4% sucrose on session 11, once the animal has detected the negative discrepancy between obtained and expected rewards. Second, if the initial downshift event is sufficiently aversive, an emotional memory may be encoded. Because this memory includes aspects of the animal's own emotional reaction to the downshift, it is called *egocentric memory*. Third, every time the animal tastes the downshifted solution a process of memory update would adjust the expectancy learned during pre-shift sessions (32%) to the new value (4%). Because this memory encodes information of the new reward, it could be called *allocentric memory*—a memory of the environmental change. Allocentric memory would reduce and eventually eliminate the negative discrepancy. Fourth, during downshift sessions, there is the inevitable pairing between negative emotion and 4% sucrose, which, although less than expected, it is still rewarding, especially for a food-deprived animal. Such pairings would result in a *counterconditioned memory* of negative emotion, a process that would attenuate rejection and promote approach to the downshifted solution (Amsel 1992). Therefore, allocentric memory and counterconditioning should both contribute to the recovery of consummatory behavior to the level of unshifted controls.

Research has attempted to provide evidence for these memory processes in experiments with a variety of designs, for example, by varying the retention interval between the last pre-shift session and the first postshift session. Flaherty (1996, pp. 40–42) summarized several studies with retention intervals ranging between 1 and 32 days, suggesting that between 10 and 17 days, the cSNC effect is attenuated by the interval. He suggested that long retention intervals weaken

the memory of the pre-shift solution, thus attenuating contrast.

Theoretically egocentric and allocentric memories are formed somewhat simultaneously during the initial downshift session. Whereas the former encourages behavioral suppression, the latter prompts the animal to consume the downshifted reward. Therefore, the cSNC effect should be prolonged either by enhancing egocentric memory or by interfering with allocentric memory, whereas the cSNC effect should be reduced either by interfering with egocentric memory or by enhancing allocentric memory. Following this rationale, memory enhancers such as corticosterone (a stress hormone) and D-cycloserine (an NMDA-receptor partial agonist) administered immediately after the first downshift session prolong the cSNC effect in subsequent sessions (see Papini et al. 2015). It is hypothesized that corticosterone and D-cycloserine enhanced the reactivation of the egocentric memory of the reward devaluation. Posttraining administration of benzodiazepine anxiolytic chlordiazepoxide also extends cSNC. Because chlordiazepoxide has a memory-interfering effect, these results were interpreted in terms of disruption of allocentric memory.

Counterconditioned memory can be studied by assessing transsituational transfer effects. Amsel (1992) argued that partial reinforcement training counterconditions a frustration response that increases persistence during extinction. Furthermore, the reactivation of frustration in other situations would induce persistence even in the absence of partial reinforcement training. Consistent with this view, partial reinforcement training during pre-shift trials (random mixture of 32% sucrose and water sessions) attenuates the cSNC effect after a 32-to-4% sucrose downshift. In addition, anxiety-prone rats (RLA-I) trained in the cSNC situation later exhibit a reduced iSNC effect and, vice versa, first trained in iSNC later reduced the cSNC effect. Interestingly, such transfer effects were not observed in the RHA-I strain (Cuenya et al. 2015). Thus, it appears that recovery from one situation involving incentive relativity and negative emotion may attenuate the impact of an analogous manipulation under different conditions.

## Anticipatory Negative Contrast (ANC)

ANC was first observed in the course of a study investigating whether conditioning could affect the glucoregulatory system. Animals were exposed to pairings of saccharin as the conditioned stimulus (CS) and sucrose as the unconditioned stimulus (US). As a consequence of such pairings, the intake of saccharin was reduced when it served as a predictor of sucrose, suggesting that incentives can influence behavior in an anticipatory manner (Flaherty 1996). The occurrence of ANC is paradoxical with respect to a simple application of the law of effect and from a reinforcement perspective: following a behavior with a preferred substance should increase, not decrease, the initial behavior. In fact, if one alters slightly the procedure to produce ANC, the opposite result (referred to as positive induction) may occur. For example, if rats are trained to press a lever to obtain a low-valued food reward, the rate of responding for this reward increases if a high-valued food reward is available within the session. For example, animals decrease their consumption of a 1% sucrose when the solution is followed by access to a 32% sucrose, but the same animals increase their rate of operant lever pressing for a 1% sucrose if a 32% sucrose or food pellet is upcoming (King et al. 2002).

When ANC is obtained, the most common interpretation assumes that it represents Pavlovian conditioning in which the initial substance functions as a CS and the second one as a US. After several pairings, the CS would enter into an association with the US, enabling the animals to learn predictive relationships and reducing the hedonic value of the first solution (Flaherty 1996). However, alternative explanations based on the insensitivity of ANC to devaluation of the preferred substance have also been proposed. For example, Onishi and Xavier (2011) argued that ANC depends on two memory processes: (1) the memory of the relative value of the first solution (which is daily updated on the basis of gustatory and/or post-ingestive comparison of the first and second solutions) and (2) the memory of past pairings.

## Detection

Many studies focusing on the factors influencing the detection of disparities between rewards suggest that the ANC effect depends on the absolute and relative incentive value of the first and second rewards, their hedonic/nutritional properties, and the temporal interval between reward presentations. The first evidence of this phenomenon involved the use of a 0.15% saccharin solution available for 3 min and followed after an inter-solution interval of 5 min by a 32% sucrose solution for 5 min. Control groups received either 2% sucrose as the second solution or only the 0.15% saccharin. After 12 sessions, groups receiving saccharin only or saccharin followed by 2% sucrose showed a more accelerated lick function as compared with animals receiving 0.15%–32% pairings. This result was interpreted on the basis of the greater hedonic value of 32% sucrose solution compared to the 0.15% saccharin (see Flaherty 1996). However, the question remained whether this phenomenon was anticipatory (i.e., based on the anticipation of the impending sucrose) or successive (triggered by the comparison between the current 0.15% saccharin and the 32% sucrose presented as the second reward on the previous day). Several experiments discarded the latter interpretation. First, increasing the inter-solution interval from 5 to 30 min significantly reduced the suppressive effect of 32% sucrose on saccharin intake. Additional support for a within-day anterograde process was reported by Flaherty and Rowan (1985), who conducted a within-subjects study in which both the contrast (0.15%–32%) and the control (0.15%–0.15%) conditions were presented to the same subject in alternation across days. The rationale behind this experimental design was as follows. If contrast is based on the 32% sucrose presented on the previous day, then lick rates for the initial 0.15% saccharin solution should be lower on days when the animals received the 0.15%–0.15%, provided that these days always follow a 32% sucrose trial. By contrast, if a within-day anticipation is involved in ANC, then the lick rate for the 0.15% solution should be lower when the 0.15% saccharin predicts 32% sucrose. The results indicated that rats licked less for the 0.15% saccharin on

0.15%–32% days than on 0.15%–0.15% days. The differences between trials appeared regardless of the inter-solution interval (15 s vs. 1 min) and even after reversing the cue-solution pairings.

Once it was demonstrated that ANC depends on anterograde mechanisms, subsequent experiments showed that variations in either the first or the second reward influence the size of the effect (see Flaherty 1996). For example, when the initial substance has low hedonic value relative to the second one (e.g., water or an empty tube followed by 32% sucrose), positive induction is observed. Increasing the hedonic value of the first solution resulted in ANC, rather than positive induction. The greater the hedonic value of the first solution, the sooner and the larger the ANC. However, when other reward combinations are used the results are far from conclusive.

In addition to their gustatory/hedonic properties, differences in nutritional load between rewards may also influence the ANC effect in a complex manner. Moss et al. (2002) systematically studied the relative contributions of hedonic/gustatory properties and nutritional loads to the ANC, by replacing the first 0.15% saccharin solution with soy milk. Soy milk has a greater hedonic value than sucrose (16%), but similar nutritive properties. According to the hedonic disparity hypothesis, ANC should have been found when using sucrose-soy milk pairings, but not soy milk-sucrose pairings. Contrary to what was expected, the sucrose-soy milk sequence failed to produce ANC, whereas the soy milk-sucrose sequence did yield a reliable suppression of soy milk intake, showing a direct function of the sucrose concentration. Taken together, these results reveal the complexity of the factors taking part in the detection of reward disparity in the ANC paradigm.

### Motivation

Apart from the hedonic properties, the rewards, their caloric value, and the temporal presentation pattern, ANC is also modulated by motivational factors (see Flaherty 1996). Some studies have explored how food deprivation influences animal's behavior in anticipatory situations. In food-deprived animals, ANC was obtained when 2% or 4% sucrose preceded by 15 s, but not by

5 min, access to 32% sucrose. In nondeprived animals, the reduced intake of either 2% or 4% sucrose appeared whenever these rewards were presented 5 min before 32% sucrose. Interestingly, the influence of the deprivation condition was not observed when saccharin-sucrose pairings were used, suggesting that the caloric value becomes important with long inter-solution intervals under conditions of food deprivation.

The level of deprivation has also been investigated by Weatherly et al. (2005), who found that deprivation promoted positive induction, rather than ANC. Induction was observed when subjects were food deprived and exposed twice a day to 1% sucrose (3 min) followed (after 0, 15, or 60 s) by a 3 min access to 32% sucrose. However, nondeprived animals did not show either a reliable positive induction or an ANC effect. The authors concluded that although induction was never observed when subjects were not food deprived, eliminating food deprivation was not sufficient to produce contrast.

A different approach to address the issue of how motivation impacts ANC involves using rewards with high incentive value, such as abuse drugs. The model was initially based on the frequent observation that rats avoid the intake of a gustatory CS such as saccharin after it has been paired with an aversive US (e.g., the toxin lithium chloride). Drugs of abuse (e.g., cocaine, morphine, heroine) also suppress saccharin intake following repeated pairings. Based on its similarity with conditioned taste aversion procedures, this effect was initially interpreted as indicative that abuse drugs have both reinforcing and aversive properties. However, the suppressive effects of drugs of abuse differ in many ways from those of aversive stimuli, leading to an interpretation of this phenomenon based on reward comparison: Rats would decrease saccharin because its value is outweighed by that of a highly reinforcing psychoactive drug (Grigson 1997).

As opposed to ANC tests, in which free access to both rewards is the standard procedure, drug-induced suppression of CS intake usually involves forced administration of the US. Despite such differences, the suppressive effects of abuse drugs and sucrose on CS intake share a number of similarities: (a) both depend on

the nature of the gustatory CS; (b) both are attenuated by food deprivation; (c) both are greater in selected rats highly reactive to abuse drugs (Lewis rats); (d) both are increased in rats exposed to chronic morphine; and (e) both are disrupted by lesions of the gustatory cortex and gustatory thalamus (Grigson 2008). Overall, the data suggest that both behavioral phenomena are related to mechanisms of anticipated reward comparison and devaluation. Supporting this contention, recent results showed that a reduction in CS intake induced by a single saccharin-morphine pairing is accompanied by a marked blunting of the nucleus accumbens dopamine response to the saccharin reward cue (Grigson and Hajnal 2007).

### Emotion

While hedonic devaluation provides a parsimonious explanation of ANC, alternative mechanisms have also been proposed. One possibility is that the presentation of a low reward after being paired with a high reward triggers negative emotion (Flaherty 1996). While there is evidence for such a mechanism in other forms of contrast (as in SNC, see above), three sources speak against this possibility in the case of ANC (Flaherty 1996; Papini et al. 2015). First, anxiolytics (such as chlordiazepoxide, cyproheptadine, buspirone, and testosterone) fail to affect ANC. Similarly, the administration of drugs known to enhance aversive memories of reward downshift events (such as corticosterone), do not influence ANC. The pharmacological manipulation of opioid receptors (known to be involved in psychological pain) also shows negative results when applied to the ANC effect (Katsuura and Taha 2014).

Second, lesion studies involving brain regions known to regulate negative emotions fail to alter ANC. Unlike cSNC, neither electrolytic lesions of the central nucleus of the amygdala (see Flaherty 1996), nor the transient inactivation of the centromedial region of the amygdala induced by lidocaine microinfusions affected ANC (Kawasaki et al. 2015).

Third, studies based on comparisons between strains of rats that differ in emotional reactivity are not conclusive with respect to

ANC. Maudsley reactive (MR) and Maudsley nonreactive (MNRA) rats showed little difference in ANC when licking frequency was used as dependent variable. However, whereas MNRA rats exhibited longer latencies to lick 0.15% saccharin when this solution was followed by 32% sucrose, a positive induction effect was found in the MR strain (Flaherty 1996). Regarding the extensively phenotyped RHA-I and RLA-I rats in anxiety tasks, no differences in ANC were found (Torres and Sabariego 2014).

Taken together, these data suggest that ANC situations may not involve negative emotion. However, this conclusion should be taken with caution. For example, Gómez et al. (2000) explored whether individual differences in saccharin intake suppression induced by morphine correlated with circulating corticosterone levels. Greater suppression of CS intake was associated with higher corticosterone levels. In the same vein, McFalls et al. (2016) found that those animals exhibiting greater levels of saccharin intake suppression showed increased mRNA expression for elements of the stress/CRF signaling pathway within the hippocampus, medial prefrontal cortex, and ventral tegmental area.

### Memory

Since its discovery, the ANC effect was thought to be due to Pavlovian associations and anterograde memory processes, both involving the anticipation of the highly preferred sucrose reward when the less preferred saccharin solution is presented. A few studies have addressed the neurobiological basis of the memory processes that support ANC. Electrolytic lesions of the gustatory thalamus impaired ANC but had no influence on simultaneous contrast (Reilly et al. 2004). These results suggest a role of the gustatory thalamus in the comparison between the value of an available reward and the memory of a preferred reward that is anticipated in the near future.

The gustatory insular cortex has also been involved in reward anticipation. Kesner and Gilbert (2007) found that quinolinic acid lesions of the agranular insular cortex disrupted ANC in rats receiving 2%–32% sucrose pairings in their home cages. The fact that animals did not show any deficit in the discrimination between both

solutions (as shown by preference testing) suggests that the gustatory insular cortex may be involved in memory and reward anticipation. Finally, ANC has been proposed not to depend on anticipation of the second reward since it is insensitive to the devaluation of the second reward (Onishi and Xavier 2011). According to this view, the relative incentive value of the first solution would be estimated on the basis of the memory of past pairings, as well as on daily updating based on both gustatory and/or post-ingestive comparisons between solutions.

## Conclusions

The scenarios proposed at the start of this entry on incentive relativity illustrated daily life situations that are simulated in the lab with animal models. Thus, Helen's disappointment when her date did not resemble what she had seen in a picture is an example of SNC. High expectations based on prior experience led to negative emotion, just as expecting 32% sucrose induces frustration when a rat encounters 4% sucrose instead. Tom's problem was akin to ANC. His taste for sweets was reduced when they were paired with opioids, much like anticipating 32% sucrose reduces intake of the lesser-valued 0.15% saccharin. The study of incentive relativity offers an inroad to understand these distortions of reward value.

The study of incentive relativity is providing some insights into several issues of basic and translational importance. Something these effects have in common is their connection to a wide range of psychological processes, despite being produced by seemingly simple situations. Three areas are highlighted here.

First, SNC effects, both instrumental and consummatory, have been studied more extensively from comparative and developmental perspectives. The SNC effect is not a general phenomenon among vertebrates. It has been reported in several species of mammals (e.g., rats, mice, monkeys, dogs, and opossums), but it has failed to occur in studies with pigeons, reptiles, amphibians, and fish (Papini 2003). Similarly, the iSNC effect emerges around 24 days of age in rats, in

correlation with the maturation of the hippocampal formation (Amsel 1992). There are no similar comparative data on the ANC effect.

Second, the SNC has become a model to study the consequences of negative emotions. The main idea is that the reduction of an incentive is analogous to an experience involving loss. Experiments show that such experiences may distort sensitivity to peripheral pain, are influenced by manipulations of pain-related systems in the brain (e.g., opioid and cannabinoid receptors), are modulated by tranquilizers, and are affected by lesions in brain sites known to be connected to emotional responses (Papini et al. 2015). These studies have implications for an understanding of how an experience of loss may affect both the emotional and health spheres of human functioning.

Finally, both SNC and ANC provide useful paradigms to model the connection between incentive relativity and addictive behavior. SNC promotes the voluntary oral consumption of anxiolytics capable of reducing negative emotions – an emotional self-medication effect (Ortega et al. 2017; Torres and Papini 2016). Since anxiolytics such as ethanol and benzodiazepines have addictive potential, this effect offers a possible view of the initial stages of addictive behavior. ANC offers insights into how drugs devalue natural rewards and also how natural rewards may help protect individuals against drug misuse and abuse (Grigson 2008).

## Inclusive Fitness

Anna Szala and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

[Altruism](#); [Darwinian fitness](#); [Hamilton's paradigm](#); [Hamilton's rule](#); [Kin selection](#)

## Definition

Inclusive fitness is a method of measuring evolutionary success. It is the ability of an individual to

transmit genes to the next generation, including genes shared with relatives. In accordance with this rule, an individual's inclusive fitness can depend, in part, on altruistic behavior and cooperation. The term *inclusive fitness* was introduced in 1964 by William Donald Hamilton, an English evolutionary biologist. Hamilton distinguishes two types of fitness: (a) direct fitness, defined as the number of offspring produced directly by an individual, regardless of who rears, supports, or rescues the offspring; and (b) indirect fitness, defined as the number of related individuals produced, multiplied by the degree of relatedness of those individuals (Hamilton 1964a, b). Inclusive fitness is defined as an individual's direct fitness plus an individual's indirect fitness.

In the above-mentioned definition, one offspring is defined as an individual's own child, which shares 50% the individual's genes, in sexually reproducing species. Following this logic, a sibling's child, which shares 25% of the individual's genes, is half an offspring equivalent, and a cousin's child, which shares 6% of the individual's genes, is an eighth of an offspring. From a gene-centered perspective, evolutionary success is achieved when a gene has a relatively high number of copies in the population. It can be achieved by producing one's own direct offspring, and/or by helping kin produce offspring.

## Introduction

Hamilton's calculations showed that passing a gene to one's offspring is not the only way of successfully transmitting it to the population. Another way of transmitting copies of a gene is by promoting survival and reproduction of those sharing copies of the gene by descent. The latter process is called *kin selection theory*, or *inclusive fitness theory*, and it is a key mechanism affecting the evolution of social behavior. For example, yellow-bellied marmots put themselves in danger and attract a predator's attention by producing loud calls warning their social group (usually consisting of related individuals) about danger (Blumstein et al. 1997). This seemingly

counterproductive behavior has evolved because ensuring the survival of kin will increase an individual's overall, inclusive fitness.

## Hamilton's Rule

The introduction of the concept of inclusive fitness helped to explain the prevalence of behaviors often perceived as altruistic. Hamilton argued that supporting kin increases one's evolutionary success by the mechanism of inclusive fitness, not direct fitness. For example, in ground squirrels, calls warning others about approaching predators occur most frequently if relatives of the calling individual were around (Milius 1998); in red squirrels, females adopt orphans only when they are related to them; adoptions were never observed for non-kin (Gorrell et al. 2010); and in humans, when declaring willingness to help children, close relatives are preferred over distant relatives, and distant relatives are preferred over unrelated children (Antfolk et al. 2017). That means that natural selection favors organisms behaving in a way that leads to increases in inclusive fitness, and also ensures that the helper's "altruistic" gene (or complex of genes) is more widely present in the next generation. Hamilton developed a simple formula ( $c < rb$ ) for calculating whether a gene "for" altruistic behavior will become more widespread in the population. The formula calculates whether the actor's reproductive costs incurred by displaying altruism are lower than the degree of relatedness times the reproductive benefit to the recipient. If it is, then it will be beneficial for the actor and, therefore, help in spreading the relevant gene(s) in a population.

Another concept important for understanding inclusive fitness is the *green-beard effect*, a thought experiment explaining selective altruism, a way of recognizing behaviors considered altruistic, expressed by unrelated individuals willing to provide support. The idea of the green-beard effect is that a gene or genes (i.e., those coding the hypothetical green beard) must produce a recognizable phenotype that is preferentially treated by individuals with the same gene.

## Incomplete Penetrance

Ali Marchant and Kristine O. Evans  
 Department of Wildlife, Fisheries and  
 Aquaculture, Mississippi State University,  
 Mississippi State, MS, USA

## Synonyms

[Reduced penetrance](#); [Variable expressivity](#)

## Definition

Incomplete penetrance occurs when individuals with a certain genotype in a population do not necessarily express the associated phenotype.

## Introduction

Incomplete penetrance is a phenomenon of interest to many geneticists, with particular emphasis on disease expression. It occurs in genes of many animals, including humans, and is common with autosomal dominant diseases. However, it can also be found in recessive patterns of inheritance, though this is rare. Expression of a phenotype is most likely a result from many factors, including: genetic, environmental, and lifestyle. With a wide variety of factors influencing incomplete penetrance, current research focuses on individual expression of disease phenotypes, as well as carrier genotypes where phenotypic expression may not occur until the next generation of offspring. Incomplete penetrance of genes also renders prediction of disease expression among members of a population or family difficult (Field 1970).

## Case Study: Inbred Mice Study with Mutated Collagen Gene (COL1A1)

Pereira et al. (1994) conducted experiments to assess the risk of Osteogenesis imperfecta by examining the severity of spontaneous bone fractures in inbred mice as a result of incomplete penetrance caused by a mutated collagen gene. They hypothesized that uterine position may be a factor in explaining the variability in phenotypic expression but found there was only a slight effect of uterine position. Severe and minimally affected individuals were equally distributed in the uterine horns of female mice, and the “normal” individuals (i.e., those lacking bone fractures) were positioned primarily at the base and lower regions of the uterus. The researchers also found that incomplete penetrance of spontaneous fractures was not explained by levels of gene

expression or variations in genetic background, but instead caused by an “inherent feature of expression of a mutated collagen gene” (Pereira et al. 1994).

### Case Study: Management of the Blindness of Wolves Bred in Captivity

Many captive-bred wolves in Scandinavian zoos were born blind in the 1960s and 1970s. The first blind wolf from the population was found in 1967, but the breeders continued using the animal's siblings in the breeding program. In the early 1990s, Laikre et al. (1993) found the primary issue was a lack of pedigree management, which may have caused a reduction of genetic variability and increased prevalence of founder alleles for blindness in the captive population. Laikre et al. (1993) found that removing high-risk carriers for the founder allele for blindness and decreasing inbreeding is a good management approach to decrease phenotypic expression of blindness without severely affecting other founder allele survival (loss of genetic variation) in the wolf population.

### Conclusion

Lack of consistency in incomplete penetrance makes it difficult to predict future mutations or disease expression in some species, including humans. Animals bred in captivity may be especially prone to problems with incomplete penetrance due to inbreeding of genetic lineages. In cases with incomplete penetrance, predicting members of a population that will express a disease, or which individuals are at risk for passing the disease onto their offspring can be difficult. Animals carrying alleles for a mutation or disease but who have not expressed the phenotype may be at risk for passing on those alleles to offspring if they are bred with another animal with the same alleles at the target loci. For autosomal dominant diseases, only one parent needs to have the genotype for the disease (AA, Aa), while homozygous recessive genes (aa) requires both parents to carry a portion of the recessive disease.

## Definition

Incubation behavior is the active transmission of heat from parent to embryo to foster development.

## Introduction

Oviparity, in which a large component of development occurs in an egg outside the female body, is commonly accepted as the mode of reproduction ancestral to all animals. Although the occurrence of embryonic development outside the female body offers enhanced adult mobility and predator avoidance, the laying of eggs in a discrete location leaves embryos exposed to predators and potentially harsh environmental conditions. Thus, tending to eggs in some way, so as to enhance offspring survival, may arguably be the most widespread form of post-fertilization parental care in the tree of life (Smiseth et al. 2012). During this time, eggs must be kept at optimal environmental conditions to facilitate embryonic development. These conditions include temperature, humidity, and egg positioning and, generally, are maintained by a range of behavioral adaptations, which vary across taxa and environmental conditions.

Like any series of chemical reactions, growth occurs most rapidly at an optimal temperature, and its speed declines at either extreme. Behaviorally, incubation in terrestrial vertebrates typically refers to a form of egg attendance in which developing embryos experience an amount of heat and humidity that are under parental control and generally much less variable than expected under prevailing environmental conditions. In many groups, the environmental conditions to which embryos are exposed can be held relatively constant by burying eggs underground. With few exceptions, eggs of ectotherms do not require as much energy and maintenance of optimal conditions as do the eggs of endotherms. For example, many reptilian species abandon their eggs after laying, but females might nevertheless control the temperature at which embryos develop indirectly through choice of an oviposition site, which, in turn, can shape offspring sex ratios (i.e., temperature-dependent sex determination). In other reptiles, the incubation period entails

protection from one or both parents, with temperature control being a co-evolved benefit.

Generally, species that incubate their eggs fall into two main categories: (i) external incubators in which embryos develop within eggs laid outside the body and (ii) internal incubators in which development occurs in eggs that remain inside the body (i.e., ovoviviparity). Internal incubators include mouth-brooding fish and a host of invertebrates (where “brooding” is usually used synonymously with “incubating”) and prototherian mammals (development within the duck-billed platypus begins with internal, followed by external, incubation) and may even occur briefly in a few species of modern bird (Birkhead et al. 2010).

For most birds, little embryonic development within the egg occurs during egg production, until the onset of incubation. Incubation denotes the period of time when parents warm their eggs directly by sitting atop them. During the breeding season, the sex that incubates has a brood patch on the abdomen – an area that lacks feathers to allow for direct skin contact with the eggs. The brood patch facilitates more efficient heat transfer from parent to eggs. There are some exceptions to this type of incubation; for example, many megapode species bury their eggs in a pile of leafy vegetation, and incubation is accomplished via the warmth produced by decomposition of the vegetation. Additionally, species in hotter climates must shade their eggs during incubation to ensure they do not overheat. The optimal temperature for developing embryos varies widely across species, with some having a larger range of tolerable temperatures. Despite this variability, all species show increased sensitivity to hyperthermia compared to hypothermia.

Incubation also requires maintenance of humidity since relative humidity can influence embryo temperature, with the optimal relative humidity to ensure hatching between 40% and 70%. While desiccation would be detrimental, some water evaporation from the egg during incubation is essential; an air pocket within the egg increases in size during incubation to allow direct oxygen exchange between embryo and environment and facilitate successful hatching.

Avian incubation also requires the periodic turning of eggs within the nest, especially early

in the incubation period. Egg turning prevents adhesion of the embryo to the shell membrane, aids in fluid transport and embryonic growth, and increases the hatchability of eggs. Rates of egg turning differ between species, with the eggs of precocial species requiring less turning than altricial species due to the albumen content within the eggs. Egg turning allows the embryo to successfully utilize the fluids and proteins within the albumen. The eggs of altricial species tend to have a higher albumen content than those of precocial species, which explains why they must be turned more frequently (Deeming, 2009). Contrary to avian eggs, reptilian eggs do not require turning during incubation, and egg turning can be detrimental to embryos in some cases.

Incubation duration ranges from as short as 10 days in brood-parasitic passerines to up to 84 days in larger species. Duration of the incubation period depends on environmental conditions but also on parental behavior. Incubation constancy, or the amount of time the eggs are tended to versus left exposed, can be an effective method of maintaining embryonic temperature. In warmer conditions, parents tend to reduce the number of on-off bouts, remaining away from the nest for longer periods of time (Mueller et al. 2019). Properties of the clutch can also impact incubation duration. Due to the physics of heat loss, larger clutches and smaller eggs typically require a longer incubation period than smaller clutches and larger eggs (Williams 1996).

## Incubation as a Conceptual Framework

Like all of animal behavior, the study of incubation in itself is valuable to advancing human knowledge, whereas, perhaps more importantly, understanding the natural history of incubation also provides a useful context in which to explore more general questions in animal physiology, ecology, and evolution. For example, by controlling incubation behavior, parents in many bird species may exert fine control over offspring development depending on the onset of incubation relative to clutch completion. The mechanisms behind avian ovulation and egg laying

dictate that clutch completion cannot occur instantaneously; at least a day, or more in many species, elapses between the laying of subsequent eggs. Consequently, initiating incubation behavior prior to clutch completion causes some embryos to begin development earlier than their slightly younger siblings, thereby creating a size hierarchy early in life that has consequences for offspring fitness (Mock and Parker 1997).

The role of prolactin and other hormones, including glucocorticoids, in regulating the onset of incubation, also provides a useful context in which to understand parental investment and physiology, the costs of reproduction, and intersexual selection (Williams 2012). Most forms of parental care are usually assumed to be costly, and these costs may affect the fitness of males and females in different ways. Although both male and female parents incubate eggs in some species, the sexes differ considerably in incubation behavior, even in species with biparental incubation; in others, only one parent (usually the female) is responsible for all incubation effort (Skutch 1957).

It has been debated whether the incubation period is costly for parents in terms of the amount of investment required. There is a necessary trade-off between the amount of time a parent is able to spend incubating versus foraging and an increase in metabolic rate to raise body heat to warm the eggs (Reid et al. 2002). Despite this, recent studies have shown that the incubation period may serve as a beneficial period of recuperation for parents before the extremely costly period of young rearing (Sakaluk et al. 2018). Ultimately, the costliness of incubation depends on the life history of the species, including nutritional and health requirements, the mating system, and environmental conditions.

Incubation behavior represents a relatively simple behavioral modification applied to an ancestral mode of post-hatching parental care. External incubation is especially adaptive in birds through reduction of flight costs associated with carrying a brood of developing embryos within the body, and results of experimental studies indicating uncertainty associated with costs of incubation further suggest an advantage associated with external incubation in flying endotherms. Future research utilizing incubation as a context

for investigating general problems will shed further light on our understanding of animal behavior and evolution.

## Indicator Species

Lisa Lauderdale  
Chicago Zoological Society – Brookfield Zoo,  
Brookfield, IL, USA

## Synonyms

Bioindicator; Biomonitor; Ecological index; Environmental index; Proxy species; Sentinel species; Surrogate species

## Definition

Indicator species are one or more taxa whose relative absence, presence, or abundance serves as measure of the health of a given ecosystem.

## Species as Indicators

Species can serve as biological indicators of ecological health and have a number of distinct uses. In recent years, the use of the term “indicator species” has been widely adopted by researchers, and the concept has been adapted and applied to a range of scientific assessments. Researchers use indicator species’ relative absence, presence, or abundance as a representation of an environmental trait or condition. Their status is used as both an ecosystem monitoring and management tool by ecologists and biologists alike.

Using a single species, or group of species, as a proxy of environmental health provides a reliable, cost-effective, and efficient method for studying a complex system. Ecosystems are generally comprised on innumerable species and each of these species has a complex network of interactions. More than 1.5 million species have been

described, and many more are described each year (Roskov et al. 2017). Attempting to qualify and quantify every species and its corresponding web of interactions would be a lofty, if not impossible, task.

Species designated as “indicators” are selected to describe or monitor environmental events, the current environmental state, or its changes over time. Primarily, researchers use indicator species to monitor overall ecosystem health and environmental integrity (Siddig et al. 2016). This can include reflecting both biotic and abiotic components of ecosystem states or representing the biodiversity of other taxa within the area. Indicator species are also used to reflect both positive and negative environmental change and microclimates. Changes in the status of an indicator species may be a result of environmental degradation, climate change, pollution/contamination, another species distribution, or habitat restoration. Finally, indicator species are occasionally studied as a preventative measure to monitor for early warnings of environmental change.

## Species Selection

The term indicator species can refer to a single species, multiple species within a taxon, or several species across taxa. Most often, researchers use groups of species within and across taxa as ecological indicators rather than a single species (Siddig et al. 2016). Using species groups is advantageous because they cover a larger range of ecological properties. This robust range provides redundancy to even out potential normal variation or fluctuations in the measurement of choice. Larger data sets also open up the possibility to utilize a suite of statistical analysis tools and allow for comparisons across data sets. Multi-species indicator studies are also a precaution in the event of the local extinction of one species as the other species can continue to be assessed.

While there are many advantages to using species groups as indicators, there are situations in which using a single species is beneficial. More detailed information can be collected if only one

species is being studied. Detailed data on the developmental stages or reproduction rates could result in discoveries that would otherwise be overlooked. Another benefit of using a single species is that they require fewer resources to monitor. Studies on a smaller scale are more feasible and cost-efficient than large-scale investigations. Information about single species is also more easily related to and accepted by the public, especially when the chosen species is well-known and charismatic.

Species are selected by researchers based on their ecosystem and topic of interest. There are several common selection criteria to be considered when choosing an indicator species. The species must first be readily present in the area of interest and easy to locate. The ecological data obtained from these species must be available and reliable. Often they are stenecious or live only within a certain habitat range. Indicator species must also be able to be assessed in a standardized manner. Selected species must be moderately tolerant by being both sensitive and hardy. To represent an ecosystem, they must be sensitive to unusual environmental changes but not strongly influenced by normal fluctuations (Dale and Beyeler 2001). Environmental conditions must be reflected in the species’ behavior and physiology, ultimately affecting their health and reproduction. Some species are poor candidates because they are too adaptable and are therefore not representative of other species.

Historically, the justification for selecting a specific species or species group to be a surrogate include basing selection on previous research, ecological importance, local abundance, conservation status, or a combination of two or more of these reasons (Andelman and Fagan 2000; Siddig et al. 2016).

Not all selection criteria for indicator species are based solely on scientific merit. While indicator species are a cost-effective solution to large-scale, detailed assessments of entire ecosystems, the cost of the assessment is still of concern. Establishing efficient methods for studying ecosystems that require monitoring for extended periods of time is critical. Researchers also

consider public perception and the potential relatability of the species, specifically when indicator species are used to represent negative environmental change or to inspire habitat restoration and protection. Charismatic animals tend to garner public support as rallying points for change. Considerations can also include prior public knowledge about the species.

## Valuable Taxa

Most researchers use groups of species within or across taxa as signifiers of the ecosystem health. Plant, microorganism, invertebrate, and vertebrate taxa have all been selected as indicators (Siddig et al. 2016). Among animal taxa, reptiles, amphibians, and mammals are utilized the least, and invertebrates are selected the most as indicators. Invertebrates are often chosen to represent aquatic and wetland health. Fish tend to be selected for assessing the effects of organic pollution because most fish species are heavily reliant on dissolved oxygen in the water (Bechtel and Copeland 1970). Fish populations decline rapidly when dissolved oxygen levels decrease due to organic pollutants.

## Indicator Habitats

Indicator species are selected based on their presence in a specific ecosystem. These habitats can be chosen for many reasons including having been rarely studied, currently threatened by anthropogenic disturbances, or impacted by zoonotic diseases. Aquatic and wetland ecosystems are most commonly assessed followed by terrestrial habitats (Siddig et al. 2016). Indicator species are only occasionally used when studying atmospheric conditions. Although using indicator species as a proxy for environmental health is effective, it is important to recognize the limitations of using a single species' population trends to represent a dynamic system. Ideally, a suite of contextual data along with data from indicator species is considered before drawing conclusions.

## Indicator or Keystone Species

Keystone species and indicator species are easily confused terms. However, they represent different ecological concepts. Indicator species reflect the health of an ecosystem when researchers observe the population. In contrast, a keystone species is a species with a large influence on their environment relative to their population size. Removing a keystone species from an ecosystem would cause the ecosystem to collapse. For example, Duggins (1980) described sea otters as a keystone species in kelp forests. Sea otters are one of the few natural predators of sea urchins. Sea urchins consume the kelp forest that many species of fish use for shelter and spawning. If their population is not preyed by sea otters, they destroy kelp forests and the fish population along with them. When sea otters were almost hunted to extinction, the sea urchin population exploded and consumed vast amounts of kelp causing the fish population to decline rapidly (Duggins 1980).

## Indirect Association

Vertika Singh and Kiran Singh  
Department of Molecular and Human Genetics,  
Banaras Hindu University, Varanasi, India

### Definition

Indirect association studies refer to discovery-based approach that does not require prior information about potential disease risk loci (Roper 2004).

### Association Studies

Genetic factors play a crucial role in affecting the susceptibility of an individual toward disease pathology. However, it becomes really challenging, to identify the relevant gene, as each causal gene contributes a little to the overall heritability of a particular disease.

Genetic or candidate gene association studies offer a potentially affective platform in identifying and mapping the disease-associated genes. However, this approach can only be used to study small number of genes at a time. Genome-wide association studies on the other hand provide a large platform to study multiple genes at a time. It is used to rapidly screen markers distributed across the whole genome to identify genetic variations associated with the particular disease phenotype. Once the variants are identified, it can be used to develop various strategies which will help in detection, treatment, and prevention of the disease. Candidate gene studies utilize either association or resequencing

approaches; however, genome-wide studies include both linkage mapping and genome-wide association approach.

## Linkage Disequilibrium

Linkage disequilibrium or LD defines a non-random association of alleles located at two or more loci. This term was first used by Lewontin and Kojima in 1960 (Lewontin and Kojima 1960; Slatkin 2008). It is the property of SNPs (single nucleotide polymorphisms) that defines the degree of association of allele of one SNP with the allele of another SNP in a population. It is used to study the genetic variation in a population over time.

### Indirect Association

The presence of LD can be used to generate two possible outcomes from a genetic association study. For the first outcome, if we have a strong hypothesis regarding the association of a particular allele with disease condition, then that allele can be directly genotype. This type of approach is often referred to as **direct association**, and the genotyped SNP is called as functional SNP. However, the second possibility is that the risk SNP is not directly typed, but in its place, a tag SNP which is in high LD with the risk SNP is genotyped. This is called as **indirect association**. Tag SNPs are specifically selected to capture the variation at neighboring sites in the genome, as the alleles for these SNPs tag the nearby stretch of LD (Bush and Moore 2012). International HapMap project (Tam and International HapMap Consortium. 2003; International HapMap Consortium. 2005) and various other potential databases (Sachidanandam et al. 2001; Hinds et al. 2005) have now facilitated young researchers across the globe to select useful sets of tagged SNPs that can be used as a marker for indirect association studies.

Thus, for a case-control study of measured genotype, based on the type of exposure examined, the study can be divided into two groups,

i.e., direct association and indirect association. Direct association study on one hand relies on genetic polymorphism studies of risk SNPs of a candidate gene; indirect association studies rely on polymorphic markers of genomic region.

## Individual Recognition

Christian C. Cely and Elizabeth A. Tibbetts

## Definition

Animal social behavior depends on recognition. There are many types of recognition, including self, kin, mate, gender, friend, offspring, predator, and prey. All recognition involves (i) cue production by the signaler, (ii) cue perception and template matching by the receiver, and (iii) a behavioral response by the receiver (Sherman et al. 1997).

Multiple definitions of individual recognition have been proposed that differ slightly in their specificity and complexity. The most common definition of individual recognition proposes that

receivers discriminate a signaler from others based on the signaler's unique characteristics and associate the unique characteristics with individual-specific information about the signaler (Tibbetts and Dale 2007) (Fig. 1). For example, king penguins (*Aptenodytes patagonicus*) exhibit individual recognition because each chick has individual-specific calls (signaler's cue). Parents learn their chick's unique calls and respond in a unique way; they treat their own chick differently than other chicks (Aubin and Jouventin 1998).

Steiger and Müller (2008) proposed a less restrictive definition of individual recognition: receivers need only discriminate a signaler from others based on the signaler's unique characteristics. As long as receivers have a unique phenotype, the behavior is considered individual recognition, even if receivers associate the unique characteristics with class-specific information about the signaler. For example, if a bird has multiple chicks and learns to discriminate their own chicks from among unrelated chicks using the chicks' unique calls, this behavior would be termed individual recognition. Others would consider this offspring recognition, a type of class-level recognition, rather than individual recognition because the parents treat all their chicks similarly.

A challenge associated with Steiger and Müller's definition is that it can be difficult to assess whether or not receivers perceive cues as unique if receivers don't have unique behavioral responses. Cues that appear unique to researchers might not be perceived as unique by the receiver's sensory system. For example, computer-based

acoustic analysis suggests that the alarm calls of meerkats are individually distinctive yet receivers do not respond differently to alarm calls based on the identity of callers (Schibler and Manser 2007). How can we test if meerkats perceive the alarm calls from different individuals as unique without a unique behavioral response?

Others argue for a more restrictive definition of individual recognition that requires receivers to learn and recall multiple, unique individuals (e.g., Thom and Hurst 2004). Under this restrictive definition, king penguins would not have individual recognition because parents only learn and identify one chick at a time.

## Introduction

Individual recognition is interesting from a cognitive perspective because it is considered a relatively specific and complex form of recognition. During individual recognition, receivers must learn the unique features of conspecifics, associate the features with individual-specific information, and recall the feature/information link during subsequent interactions. Individual recognition is also interesting from a cognitive perspective because it allows the formation of individually differentiated social relationships. The potential for individually differentiated social relationships influences the type and sophistication of social interactions possible within a society (Platt et al. 2016).

In this entry, individual recognition will be addressed from both the receiver and signaler

### Individual Recognition,

**Fig. 1** The criteria for individual recognition. Signalers have unique cues and receivers behave in a unique way toward the signaler

perspectives. Receivers assess, perceive, and respond to signals. In some cases, receivers have perceptual and cognitive adaptations to facilitate accurate individual recognition. On the other side, signalers have unique phenotypes that are used for recognition. This entry will discuss the contexts in which individual recognition is used, how individual recognition varies across contexts, receiver cognitive and sensory adaptations for individual recognition, and how selection acts on the signaler to facilitate individual recognition.

## Social Contexts in which Individual Recognition is Used

### Interspecific Variation in Individual Recognition across Contexts

Individual recognition is common in social contexts when there are repeated interactions between the same target individuals and also nontarget individuals. Such situations include territoriality, dominance interactions, cooperation, providing parental care, and pair bonding (Tibbetts and Dale 2007).

Much of the earliest research on individual recognition examined recognition of territorial neighbors (originally termed “dear enemy”

recognition). For example, many birds use song to identify the identity and position of their neighbors. Birds largely ignore playbacks of neighbor songs positioned on the correct territorial boundary but responded aggressively to playbacks of neighbor songs positioned on the incorrect territorial boundary and to playbacks of stranger songs (Stoddard 1996). Individual recognition is thought to reduce the energetic costs of territorial defense by enabling territory holders to focus their aggressive efforts on non-territorial floaters instead of their less threatening neighbors (Fig. 2).

Individual recognition is also important during aggressive competition because it can reduce the costs associated with competition and stabilize dominance hierarchies (Barnard and Burk 1979). Individual recognition is likely to be beneficial when there are repeated aggressive interactions between small numbers of individuals. In this situation, learning the individual identity and competitive ability of conspecifics will provide a precise way to assess rivals without multiple fights. For example, some species of fish, including brook trout (*Salvelinus fontinalis*), individually identify rivals via scent. Trout assess relative dominance ranks based on the outcome of their own aggressive interactions as well as observations of others via transitive inference. If a fish

**Individual Recognition, Fig. 2** The dear enemy approach to testing individual recognition. White-throated sparrow (*Zonotrichia albicollis*) is less aggressive to neighbor songs on the correct territorial boundary than neighbor songs on the incorrect territorial boundary, indicating that white-throated sparrow recalls the individual identity and position of neighbors. Speakers played back

neighbor and stranger songs from the boundary shared with the neighbor (*regular*), the center of the territory (*center*), and the boundary shared with a different neighbor (*opposite*). The behavioral data are normalized composite scores for the number of flights and the closest approach to the playback speaker (Taken from Stoddard 1996)

beats rival A in a fight and then observes A win in a contest with B, the fish will correctly infer that it is more dominant than individual B (White and Gowan 2013). Transitive inference was once thought to be a cognitively complex task restricted to few taxa but has now been found in many vertebrate species with individual recognition that form dominance hierarchies (Paz-y-Miño et al. 2004). Individual recognition associated with aggressive competition is widespread in nature, as many species use individual recognition to minimize the costs of conflict (Barnard and Burk 1979).

Although cooperation can occur without individual recognition, there is much evidence that cooperative behaviors such as reciprocity, alliances, social prestige, punishment of non-cooperators, and image scoring are facilitated by individual recognition. As a result, many taxa with complex social interactions rely on individual recognition. Individual recognition of group members is ubiquitous in primates and also occurs in many species that live in cooperative groups, including mammals, fish, and birds (Sharpe et al. 2013). Although social insects have complex social behavior, individual recognition is relatively rare in social insects. Instead, most social insect societies rely on class-level recognition and self-organization to produce apparently complex behavior with little individual cognitive investment.

Individual recognition is involved in multiple aspects of reproduction, including parent-offspring interactions and monogamous pair bonding. Individual recognition during parental care is particularly likely to occur when there is potential for confusion among offspring, such as among organisms that breed in high-density groups with synchronous reproduction and reduced recognition potential based on positional information. For example, the Australian sea lion *Neophoca cinerea* reproduces in large colonies. Both mothers and pups use individual-specific calls to find each other after the mother's foraging trips (Charrier et al. 2009). Monogamous species with biparental care use individual recognition to maintain pair bonds and mate guard and defend territories. For example, *Chaetodon multicinctus*

butterfly fish uses visual and olfactory cues to discriminate their mate from non-mates (Boyle and Tricas 2014).

Individual recognition during monogamous pairing and parent-offspring recognition is sometimes considered simple forms of individual recognition because receivers need only learn and recall one individual. Some argue "true" individual recognition requires receivers who can individually discriminate many individuals (Thom and Hurst 2004). As a result, future work that tests whether multiple mates, parents, or offspring can be individually identified will be useful. For example, in taxa with multiple offspring, do parents treat different offspring uniquely? For instance, there is evidence that parents of the songbird black redstart (*Phoenicurus ochruros*) respond more to the calls of the fledglings that they preferentially fed, suggesting that parents can discriminate between offspring (Draganoiu et al. 2006).

While most examples of individual recognition occur within species, individual recognition is not restricted to conspecifics. Some animals recognize individuals of other species. For example, mockingbirds learn to assess the level of threat posed by different humans. When the same human approaches a mockingbird's nest for 4 successive days, mockingbirds begin flushing from the nest when the human is a great distance from the nest and also increase alarm calling and attack flights. Mockingbird response to humans who have not threatened the nest does not change (Levey et al. 2009).

### Intraspecific Variation in Individual Recognition across Contexts

A large body of research has examined the types of social behavior associated with interspecific variation in individual recognition, but less is known about intraspecific variation in individual recognition. Examining intraspecific variation is important because responses to individual identity signals may vary across the biotic and abiotic environment. For example, a species may use individual recognition during aggressive encounters in certain social or environmental circumstances, but not in other circumstances.

Previous work has shown that there is some intraspecific variation in receiver responses to signals. For example, receiver responses to quality signals often vary with traits like sex, maturity, season, habitat, and social context. Many studies have shown that the biotic and abiotic environment influences whether females choose male partners based on sexual signals or ignore sexual signals during partner choice (Searcy and Nowicki 2005). Such variation occurs because assessing and responding to signals can be costly, so receivers will only pay attention to signals when signal response is sufficiently beneficial. Therefore, intraspecific variation in recognition may occur whenever the benefits of recognition differ across contexts.

A few studies have found intraspecific variation in individual recognition. Notably, pair-bonded male prairie voles learn to recognize individual females, while single males do not learn to recognize females. The authors found no difference in male motivation to contact females across paired and unpaired males, so they speculate that recognition differs because the social relevance of information about females varies across contexts (Blocker and Ophir 2015).

In the paper wasp *Polistes fuscatus*, the social benefits of individual recognition and receiver capacity for individual recognition vary across castes. Specifically, workers are less able to learn and remember individual conspecifics than foundresses (Tibbetts et al. [in press](#)). During social interactions, workers are unable to remember unique individuals following a 6-day separation, though foundresses remember other foundresses for 6 days. The differences in individual recognition across castes are initially surprising because *Polistes* lack discrete queen/worker castes. Workers and queens are morphologically similar, and workers can take over nests as queens. Differences in recognition may occur because the social benefits of individual recognition differ across foundresses and workers. Workers do not benefit by being individually recognizable on stable queenright nests because worker-worker aggression on queenright nests is low and workers do not reproduce or have unique roles in the colony. In contrast, foundresses benefit by being individually recognizable, as it reduces aggression and stabilizes social interactions among cooperating foundresses (Fig. 3). Individual recognition also allows foundresses to

**Individual Recognition, Fig. 3** Being individually distinctive is beneficial. Faces of *Polistes fuscatus* foundresses were manipulated so three wasps had a common, indistinguishable appearance while one wasp had a unique appearance (a, lower-right image). Distinctive

wasps received the least aggression (1, most; 4, least) in a disproportionate number of trials, indicating that a unique appearance that allows individual recognition is beneficial. Dotted line represents the expected aggression received by chance (b) (Taken from Sheehan and Tibbetts 2009)

keep track of individual social relationships, including division of aggression, food, and work (Sheehan and Tibbetts 2009).

## Complexity of Individual Recognition

There is enormous variation in the cognitive demands of individual recognition. Learning and remembering a few individuals for a short time may be relatively simple compared with learning many individuals, maintaining memories for long periods, or associating multiple types of information with individual identity. In this section, cognitively challenging aspects of individual recognition are described.

Most early individual recognition research examined how animals recognize others using a single cue in a single sensory modality. However, more recent work has shown that many animals integrate multiple cues from the same or different sensory modalities during individual recognition. For example, golden hamsters (*Mesocricetus auratus*) have multiple odor glands, and hamsters generalize between different scents from the same individual. The authors suggest that males form integrated representations of conspecifics that incorporate multiple odors (Johnston and Bullock 2001). Other species form cross-modal representations of known individuals by combining unique auditory and visual cues. For example, ring-tailed lemurs (*Lemur catta*) can produce multisensory representations by matching olfactory and visual signals to individually recognize conspecifics, though the specific proximate mechanisms that are used for sensory integration are not yet clear (Kulahci et al. 2014).

Many animals can remember individual conspecifics after a lengthy separation. For example, fur seal pups (*Callorhinus ursinus*) remember their mother's unique calls for at least 4 years (Insley 2000). Dolphins (*Tursiops truncatus*) may be able to remember unique conspecifics for decades (Bruck 2013). Male hooded warbler birds (*Wilsonia citrina*) use song to recognize their neighbors individually and are able to retain the memory after being separated for 8 months. During the

separation, birds do not sing and migrate to Central America (Godard 1991). Ravens (*Corvus corax*) remember previous individual calls after up to a 3-year separation (Boeckle and Bugnyar 2012).

Long-term individual memory may be particularly important in societies with fission-fusion dynamics, where individuals meet after unpredictably long periods of separation. Memory is also affected by the context in which the recognition is effective. For example, the mantis shrimp *Neogonodactylus bredini* can remember conspecifics for 4 weeks, perhaps because this amount of time correlates with their reproductive periodicity because female's receptivity and male-female pairing is timed with the full moon (Vetter and Caldwell 2015).

The cognitive challenges of individual recognition are also influenced by the number of individuals that are learned. African elephants (*Loxodonta africana*) have large recognition networks, as adult females can recognize up to 100 other females (McComb et al. 2000). Elephant females can recognize their own family, as well as approximately 14 other families they regularly encounter. Such impressive networks of vocal recognition may be typical of long-lived species that have fission-fusion social systems and long-distance vocal communication.

Some species learn to identify surprisingly few individuals despite apparently high levels of social complexity. For example, gelada baboons (*Theropithecus gelada*) use vocalizations for individual recognition only within the small social group known as a "unit." They do not vocally recognize other males, even males from their own band with whom they have extensive social overlap (Bergman 2010).

It is often difficult to assess whether memory constrains individual recognition. Does reduced recognition in geladas occur because males have poor memories, reduced motivation, or little social need for individual recognition? In a creative experiment, Stoddard tested whether memory constrained the ability of song sparrows (*Melospiza melodia*) to learn neighbor's songs. Song sparrows can memorize the full song repertoire of new neighbors without a decline in overall

learning performance and without forgetting the old songs, even when the number of songs learned approached the number of songs a song sparrow would have to know to make accurate discriminations across neighbors (Stoddard et al. 1992).

Another factor that influences the complexity of individual recognition is the types of information associated with individual identity cues. For example, baboons (*Papio hamadryas ursinus*) simultaneously classify other females according to dominance rank and matrilineal kinship. Associating both rank and kinship information with the unique calls of conspecifics increases the challenge of individual recognition as well as the functional complexity of social interactions (Bergman et al. 2003). To our knowledge, there is no evidence for this type of two-dimensional classification outside primates, so research in additional taxa will be important.

Some nonhuman primates use individual recognition to keep track of others' relationships. For example, baboons are more likely to approach and tolerate an opponent if they hear a "reconciliatory" grunt of a close relative of the opponent. However, "reconciliatory" grunts from individuals unrelated to the opponent have no effect on behavior. This behavior means baboons keep track of relatedness between other individuals rather than merely remembering their own relatives. Recognition of others' relationships will dramatically increase the amount of information individuals need to remember. For example, in a group of 80 individuals, a baboon who keeps track of their own relationship with each group member may only recall two pieces of information about the 79 other group members: are they related or unrelated to the focal individual and are they dominant or subordinate to the focal individual? In that same group of 80 individuals, there are 3160 possible dyad and 82,160 triad combinations (Platt et al. 2016). Current data suggests baboons can identify the relatedness and relative rank in all those potential groupings, a truly outstanding feat. In the future, additional work will be important to understand how well nonhuman species keep track of other's relationships.

## Cognitive and Sensory Adaptations in Receivers to Facilitate Accurate Recognition

Learning and remembering many unique individuals are thought to be cognitively challenging. As a result, some species have cognitive adaptations to facilitate accurate individual recognition. These adaptations fall into three categories: (1) general increase in cognitive capacity in species with individual recognition, (2) specialized increase in cognition related to individual recognition, and (3) sensory adaptations to facilitate assessment of individual identity signals.

First, individual recognition may produce generalized increase in cognitive capacity. The social intelligence hypothesis proposes that the benefits of being able to learn and remember multiple individuals and social relationships have selected for increased cognitive capacity in many social taxa (Dunbar 1998). Between species comparisons have provided consistent support for the social intelligence hypotheses. Across many taxa, species with more complex social behavior have larger brains or brain regions than species with less complex social behavior (e.g., primates, hyenas, lemurs, ungulates, carnivores, cetaceans, birds). For example, a comparative analysis in nonhuman primate species found that relative neocortical volume is linked with social group size, but not ecology, suggesting that individual social relationships are a key factor that shapes brain size evolution (Dunbar 1992).

Other analyses have found no relationship between brain size and social complexity. For example, a comparative study on brain size and social complexity in 29 species of vespids (including solitary and social wasps) showed that brain size does not correlate with colony size, social structure (hierarchies), and type of nest foundation (solitary vs. social) (O'Donnell et al. 2015). The authors hypothesized that insects can perform relatively complex tasks with minor adjustments of neural circuitry. Further, many highly social insects have been selected to have more specialized brains rather than larger brains. More generally, there is a growing appreciation

that understanding the relationship between social behavior and cognition requires nuanced assessment of social complexity that is relevant to the taxa of interest (Platt et al. 2016).

Second, some species have specific cognitive adaptations that facilitate individual recognition. *Polistes fuscatus* paper wasps use individual face recognition and are specialized for face learning; wasps learn to identify conspecific faces more quickly and accurately than other visual information. In contrast, paper wasp species without individual recognition perform poorly at face learning. A closely related wasp species that lacks individual face recognition, *P. metricus*, lacks face specialization and has trouble learning conspecific faces. The divergence in face learning between closely related wasp species suggests that face specialization in *P. fuscatus* is an adaptation to facilitate individual recognition (Sheehan and Tibbetts 2011). Face specialization in paper wasps may be associated with some neural changes in the antennal lobe and the mushroom body sub-compartments. However, there appears to be no major optic lobe specialization in species with visual individual recognition, suggesting that the visual processing capabilities of paper wasps might be preadapted to discriminate complex visual features, such that the ability to discriminate facial markings could require relatively small changes in their neuronal substrate (Gronenberg et al. 2007).

Neural specialization for individual recognition has been best studied in primates. Humans are experts at using facial features for individual recognition. Humans can learn and remember many individuals over their lifetime and only require short exposure to form individual memories. Humans also use configural processing to learn faces, as the spatial arrangement of facial features is integrated into a single “face image” rather than recognition being based on the component parts of a face. Finally, humans have neural specialization for face learning; there is a network of distributed neural regions that respond specifically to faces, not other visual stimuli. Damage in specialized area can produce individuals who are unable to recognize individual faces (Tsao and Livingstone 2008). Nonhuman primates also use faces for individual recognition

and have some specialization for face learning, including face-selective neural responses in certain regions of the brain. Some primates also use configural processing to discriminate between individual faces, though most primates rely less on configural face processing than do humans (Leopold and Rhodes 2010).

Finally, some animals have sensory adaptations to optimize assessment of individual identity signals. Paper wasps with visual recognition have larger facets in the eye’s acute zone than species without visual recognition. Larger facets improve resolution of small images, such as wasp facial signals. Therefore, the wasps’ sensory systems may evolve to optimize signal assessment (Fig. 4) (Sheehan et al. 2014). In mice, odors (major urinary protein) signal individuality. The neurons in the vomeronasal system (olfactory system) are activated selectively by odors that signal individuality and gender, suggesting an olfactory adaptation for individually recognition of conspecifics (Cheetham et al. 2007).

## Individual Recognition from the Signaler’s Perspective (Individual Identity Signals)

### Signals Versus Cues

Individual recognition can occur via signals or cues. Signals and cues are similar in that both modify the behavior of receivers. The key difference between signals and cues is that signals benefit the signaler, while cues do not (Searcy and Nowicki 2005). For example, human faces are signals that convey information about individual identity to receivers. Humans likely benefit by having unique, easily recognizable faces. As a result, human facial variation has been selected to optimize receiver recognition, and this selection has shaped human facial variation as well as the genetic regions that code for human facial variation (Fig. 5; Sheehan and Nachman 2014). In contrast, human fingerprints are a cue of individual identity. While it is possible to discriminate among individual humans based on fingerprints, variation in fingerprints is a by-product of development. Fingerprints have not been selected to

Individual Recognition,

**Fig. 4** *Polistes* wasp species that exhibit visual signal also exhibit larger facets than expected in the eye acute zone. *Filled circles*, visual signaling species; *open circles*, nonvisual signaling species. Having larger facets is considered an adaptation to facilitate recognition via visual signals (Taken from Sheehan et al. 2014)

**Individual Recognition, Fig. 5** Genomic regions associated with facial morphology show evidence of selection for individual identity signaling. Bars represent the proportion of SNPs within each minor allele frequency (MAF). Genomic regions associated with facial morphology have elevated levels of intermediate-frequency alleles when

compared with neutral regions or genomic regions associated with variation in height. The higher genetic diversity in face-associated SNPs is consistent with negative frequency-dependent selection acting on human facial features (Taken from Sheehan and Nachman 2014)

convey information about individual identity, so fingerprints and the regions that code for fingerprint variation will not have signatures of selection to optimize distinctiveness.

The distinction between signals and cues is important because signals show signatures of adaptive evolution to facilitate receiver responses, while cues do not. The following sections

describe the predicted characteristics of individual identity signals.

### Negative Frequency-Dependent Selection Acts on Signalers

Individual identity signals are expected to evolve via negative frequency-dependent selection (Dale et al. 2001). Individuals with rare phenotypes are favored by selection because they are less likely to be confused with other individuals than those with common phenotypes. There is experimental evidence in both *Polistes* paper wasps and guppies, *Poecilia reticulata*, showing that individuals with a rare appearance are favored relative to individuals with a more common appearance. For example, *Polistes fuscatus* paper wasps have highly variable facial patterns that are used for individual recognition (Tibbetts 2002). Wasps with unique faces that are easy to discriminate receive less aggression than wasps with common, less distinguishable faces. Receiving aggression is costly, so these results indicate that individuals with unique phenotypes benefit by revealing their identity (Sheehan and Tibbetts 2009; Fig. 3). Field studies have shown that guppies with rare body coloration benefit by receiving more mates than guppies with a common appearance (Hughes et al. 2013). Guppies use body coloration for individual recognition, so the mating benefit may arise through identity signaling if rare guppies are easier to learn and remember than common guppies.

Comparative work provides further evidence that individual recognition selects for increased phenotypic diversity. In paper wasps, mammals, swallows, and bird eggs, individual identity signaling is linked with increased phenotypic diversity (Tibbetts et al. 2017). This relationship is consistent with the hypothesis that social benefits of being individually recognizable favor increased phenotypic diversity in certain social contexts. For example, computer-based model has shown that egg signatures by hosts of the common cuckoo evolve surprisingly fast in the presence of brood parasites. The simulation suggests many hosts evolve unique, highly recognizable egg pattern signatures as a defense against cuckoo egg mimicry (Stoddard et al. 2014).

### Effects of Individual Identity Signaling on Phenotypes and Genotypes

Because identity signals evolve under negatively frequency-dependent selection, identity signals are expected to be highly variable and multimodal and have low intercorrelation among identity signaling traits. These predictions are developed in detail in the model by Dale and colleagues (2001). Further, in the taxa that have been tested, there is low intercorrelation among identity signaling traits (Dale 2000; Tibbetts 2002). Finally, reliable identity signals are predicted to be stable over time rather than plastic.

Theoretical and empirical work suggests that individual identity signals will be highly heritable and have low condition dependence. The few individual identity signals studied have high heritability (Dale 2000). Identity signals are also expected to have low costs associated with signal production and maintenance because phenotypes that are not costly will spread to a higher equilibrium frequency than costly phenotypes. For example, the birds ruff sandpipers (*Philomachus pugnax*) and red-billed queleas (*Quelea quelea*) live in dense aggregations in which individual recognition is key for territory defense. In both species, plumage coloration is highly heritable and has low production costs (Dale et al. 2001). Similarly, rock hyrax (*Procavia capensis*) uses the same highly variable calls for individual recognition across multiple years, and these calls are not linked to geographic locations or relatedness (Lee and Eli 2011). Paper wasps use facial patterns for individual recognition. Facial patterns are fixed during adulthood, and facial pattern development is not condition dependent, as larval diet quality has no effect on facial pattern development (Tibbetts and Curtis 2007).

Because individual identity signals are highly heritable traits under negatively frequency-dependent selection, selection for identity signaling may increase genetic diversity. Positive selection for signaling individual identity may have more widespread genetic effects than other cases of negative frequency-dependent selection because identity signaling favors high levels of variation in multiple, uncorrelated traits (Tibbetts et al. 2017). In contrast, other examples of negative frequency-dependent selection typically

maintain a limited number of morphs at stable ratios in the population.

The precise effects of individual identity signaling on the genome will differ based on the genetic architecture of identity signals (Tibbetts et al. 2017). For example, negative frequency-dependent selection acting on individual identity signals will have broader genomic consequences if signal development is influenced by many, independently segregating loci than if signal development is influenced by epistatic interactions in a small cluster of genes. Population genetic evidence indicates that negative frequency-dependent selection acting on loci that encode human facial features influences genomic diversity in humans. Specifically, loci that encode human facial features have higher nucleotide diversity than loci associated with variation in height or neutral, intergenic variation, consistent with human facial features experiencing negative frequency-dependent selection (Fig. 5; Sheehan and Nachman 2014). Further, the genomic regions surrounding areas that code for face variation also have increased nucleotide diversity, indicating that selection on human identity signals has broader effects on genomic diversity. In contrast, selection for identity signaling in mice has limited genomic consequences. Mice use major urinary proteins (MUPs) as chemical signals of individual identity. Although variation in MUPs is maintained by negative frequency-dependent selection, identity signaling in mice has little overall effect on the genome because a small number of clustered loci produce the overall MUP signature (Sheehan et al. 2016).

## Conclusions

In this entry, we consider the evolution of individual recognition from the perspective of the receiver and signaler. Studies of individual recognition from the receiver's perspective are very common and have demonstrated that individual recognition is an important aspect of social behavior in a wide range of taxa, including birds, mammals, reptiles, insects, and aquatic invertebrates. Individual recognition is also used in diverse

contexts, including territoriality, dominance interactions, cooperation, providing parental care, and pair bonding.

Individual recognition can be cognitively demanding for signal receivers, especially when receivers learn many individuals, maintain those memories for long periods, or associate multiple types of information with individual identity. Complex behaviors involving individual recognition that were once thought to be rare (e.g., transitive inference) have recently been found to be surprisingly common. Further, many taxa have surprisingly sophisticated individual recognition, including long individual memories and the ability to recall many individuals and associate diverse information with individual identities. Future research will likely continue to uncover the diversity and sophistication of individual recognition across taxa.

Individual recognition also has important selective consequences for signalers. In particular, there is growing evidence that signalers are selected to reveal their individual identity by having phenotypes that are memorably different. Individuals with rare phenotypes are favored by selection because they are less likely to be confused with other individuals than those with common phenotypes. Selection on signalers to reveal their individual identity may be an underappreciated mechanism for the origin and maintenance of phenotypic and genetic diversity. Given the growth of genomic data in non-model organisms, future work examining the genetic architecture of individual identity signals as well as the consequences of individual identity signals on animal phenotypes and genotypes will be important.

## Inductive Reasoning

Bruno Sauce and Louis D. Matzel  
Department of Psychology, Rutgers University,  
Piscataway, NJ, USA

### Definition

**Inductive reasoning** is a logical process in which multiple premises, all believed true or found true most of the time, are combined to obtain a specific conclusion or to supply evidence for the truth of a conclusion. **Inductive reasoning** is often used to generate predictions or to make forecasts. Inductive reasoning differs from deductive reasoning in that while the conclusion of a deductive inference is certain, the truth of the conclusion of an

inductive inference is only probable, where the degree of certainty is based upon the strength (or consistency) of the evidence. In other words, the conclusion of an inductive inference is not a logical certainty (such as when a meteorologist predicts snow). Inductive reasoning also encompasses most cases of where a general principle is derived or where categories are formed based on specific observations (provided that they are probabilistic in nature).

In practice, inductive reasoning is the logical foundation of science, and all fields (from physics to sociology) share the inductive method at their core. (In this regard, it is worth noting that, unlike mathematicians and logicians, scientists can never be 100% certain about their “truths” and can only make approximations based on accumulated empirical evidence.) But the application of inductive reasoning goes much beyond science and is critical for a multitude of more commonplace and prosaic activities in humans and other animals. Many cognitive activities, ranging from problem solving to social interaction to motor control, can be seen as containing an element of inductive reasoning.

## Introduction

Inductive reasoning is one of the most important and ubiquitous of all problem-solving activities, and its use by nonhuman animals is of great interest within fields of psychology and biology such as cognitive psychology, ethology, evolutionary biology, learning, and neuroscience. In its most elementary form, it seems that most animals exhibit some capacity for inductive reasoning. For instance, sea slugs respond to a stimulus inductively based on past experiences with it (e.g., by “concluding” that the stimulus can be ignored; a case of habituation). Similarly, the fear response of a rodent to a stimulus that was repeatedly and predictably presented in conjunction with a harmful outcome is to some extent the result of an inferential prediction (i.e., the rodent “concludes” by induction that a bright light always precedes a foot shock). And Pavlov’s dogs salivated in response to the ring of a bell

that always came before meal time (the dogs “concluded” by induction that bells are a signal for lunch.)

There exists, however, an old divide on the interpretation of the relevant data on inductive reasoning: Associationism holds that the data can be mostly explained by simple associative processes whereby *reflexes* are modified through experience, while rationalism holds that more complex mechanisms are involved, and the existence of inductive reasoning is required to better explain the data (see Rescorla (1988) for a more complete analysis of these contrasting views).

Traditional associationist models posit that an organism’s learned response to a stimulus is represented by the strength of the relevant associations between stimuli. In this view, the animal adapts to its environment through the process of reflex modification, and that the animal need not make predictions or choose between potential responses. In this sense, reasoning would be unnecessary to explain the examples provided above. Typically, associationists have argued that abstract, rule-governed representations do not really exist and that animals’ (and humans’) behavior can be just as well explained in terms of more specific learned associations between task inputs and outputs. Hence (according to this view), the only thing researchers should be concerned with is the specification of what gets associated with what (easier said than done, but still a relatively straightforward goal). Due in part to the predominance of associationism in psychology during the last century, it was until recently a commonplace assertion that inductive reasoning was beyond the capacity of nonhuman animals. In the past few decades, however, there has been an accumulation of evidence for animal inductive reasoning.

While traditional associationist models assume that an animal’s interaction with the environment is passive (the animal behaves by the automatic adjustment of strengths of association only in reaction to stimuli), rationalist models assume that the interaction is active – the animal actively probes the environment to make determinations about optimizing behavior (Gallistel 2003). In that framework, “figuring things out in nature” is

guided by how useful a stimulus is in reducing the animal’s uncertainty about the time of occurrence of some relevant event. This knowledge comes in part from a distribution of graded degrees of belief over a range of candidate hypotheses, or in other words, it depends on inductive reasoning. Rationalists believe that there are problem-specific computational mechanisms that evolved to inform animals’ behavior (Gallistel 2000). In this light, inductive reasoning is seen as a set of algorithms devoted to particular cognitive processes, such as causal inferences, probabilistic inferences, optimization of strategies from sampling, and categorization/concept formation (Nisbett et al. 1983). Here we will focus on these complex rational solutions that are (mostly) agreed upon to be cases of inductive reasoning.

It should be noted that the higher-order cognition proposed by rationalists and the associative rules proposed by associationists are not necessarily mutually exclusive. De Houwer et al. (2016) propose that associative learning is best thought of as an effect (i.e., the impact of paired events on behavior) rather than a specific mental process (e.g., the formation of associations). In other words, learning and behavior are mediated by higher-order mental processes akin to problem-solving processes such as inductive reasoning. (For more on that topic, see De Houwer et al. 2016).

## Causal and Probabilistic Inferences

Causal inference is the process of reasoning about a causal connection between events based on the co-occurrence of those events. As noted in the Introduction, there are many parallels between instrumental and classical conditioning phenomena in animals on the one hand and contingency assessment and causal judgments by humans on the other (see Shanks (2007) for a recent review). The scientific framework for thinking about causal inference emerged from the associationists’ work on instrumental conditioning. Nevertheless, despite the extensive evidence that bottom-up processes such as instrumental and Pavlovian learning play a fundamental role in the acquisition of causal knowledge, there is also accumulating

evidence for the involvement of top-down processes of causal induction in animals. In this light, the co-occurrence of events is not simply stimuli for an automatic association but in fact evidence for the animal's rational mechanisms to make inferences about the world.

Some interesting examples help illustrate the case that animals have the capacity for complex causal inference. Takagi et al. (2016) used an expectancy violation procedure in cats similar to what is used with human infants to probe their understanding of causal relations and physical laws. The study asked whether cats can use a causal rule to infer the presence of an unseen object on hearing the noise it made inside a container (Takagi et al. 2016). Cats were presented with either an object dropping out of an opaque container or no object dropping out after hearing either a rattling sound (by shaking the container with the object inside) or no sound (by shaking the empty container). The relation between the sound and the object matched with physical laws in half of the trials (congruent condition) and mismatched in the other half (incongruent condition). Inferring the presence of an unseen object from the noise was predicted to result in longer looking time in the incongruent condition (indicating "surprise," i.e., that the cats' expectancy had been violated). In addition, the cats were also able to predict and reach for an object appearance when the container was turned over. These results all suggest that cats have a causal understanding of auditory stimuli, which is indicative of their capacity for inductive reasoning.

In another example, Cheney et al. (1995) examined if baboons can understand cause-effect relations in the context of social interactions by using a playback experiment. Under natural conditions, dominant female baboons grunt repeatedly to subordinate mothers when attempting to interact with those mothers' infants. The subordinate mothers occasionally respond to these grunts by uttering submissive fear barks. So, in their study, Cheney et al. played causally inconsistent scenarios to the baboons in which a lower-ranking female apparently grunted to a higher-ranking female and the higher-ranking female apparently responded with fear barks. As an important control to rule out simple associative processes, baboons heard a

sequence made causally consistent by the inclusion of grunts from a third female that was dominant to both of the others. The researchers found that baboons responded very differently to each scenario: in the causally consistent scenario, they either ignored the calls or looked briefly in the direction of the speaker, while in the causally inconsistent scenario, the baboons stared (seemingly surprised) for a long time. That suggests that baboons recognize by inductive reasoning the factors that cause one individual to give submissive vocalizations to another.

Even rats also seem capable of some degree of causal reasoning. In one study, Blaisdell et al. (2006) concluded rats are able to derive predictions of the outcomes of interventions after passive observational learning of different kinds of causal models. Those outcomes, according to the study, cannot be explained by associationist models but are instead consistent with inductive reasoning models. As a last example, it is important to note that causal reasoning is also critical for the ability to adapt an object for use as a tool, a skill that has been demonstrated by many animals.

The ability to infer causation also depends on the ability to estimate probabilities, as actions (causes) do not always lead to the outcome (expected effects). Animals often face circumstances in which the best choice of action is not certain. Because of this, the ability to reason about probabilities has ecological relevance for many species. Environmental cues may be ambiguous, and choices may be risky (for a review on the theoretical side of decision-making under uncertainty, see Trimmer et al. 2011). The use of inductive reasoning to estimate probabilities requires sampling, and for that an individual must be able to estimate proportions.

Multiple species of animals seem to be able to successfully make judgments on proportions. For example, when foraging, animals go to where more will be available by considering the amount of food in alternative locations and the number of other individuals feeding at these different locations (Rugani et al. 2015). Or in a social context, some primates show inequity aversion; they are able to judge their own effort and payoff *relative* to another individual's (Brosnan and de Waal 2003).

Probabilistic inference goes one step beyond the ability to compare proportions, because the subject also needs to understand the sampling part of the procedure; that is, they need to make inferences about the probable identity of items drawn from populations, based on the distribution of items in those populations. In fact, a study on capuchin monkeys shows that some individuals could make judgments about proportions but could not reason about probabilities (Tecwyn et al. 2017). Capuchins had to select between hidden single-item samples randomly drawn from two jars. In their first experiment, Tecwyn et al. familiarized subjects with the single-item sampling procedure and determined their baseline performance in this task with two populations of items, where each jar contained only preferred or non-preferred items (100% preferred vs. 100% non-preferred), a task that does not involve any probabilistic judgment. In the other experiments, the researchers investigated the ability of the subjects to make inferences about random samples drawn from mixed pools of items in the two jars. Their results revealed that capuchins' performance suffered when the jars had mixed pools, because it required the individuals to reason probabilistically. Some individuals were still able to infer correctly, but not all did so. As the authors later discuss, this suggests that probabilistic inference might also require other complex mental processes such as inhibitory control and working memory.

Probabilistic inferences are not only restricted to apes. Even mice, for example, possess at least a simpler form of that capability (Berkay et al. 2016) and can adaptively modulate their decisions based on their experienced probability of outcomes. Probabilistic inference also seems to play a critical role in animals' social behavior, including decisions made according to game theory (Crowley 2003).

### Optimization of Strategies from Sampling

The capacity of sampling for probabilistic inference is also related to an inductive inference of integrating information together, such as when an

animal navigates home by triangulating spatial cues or develops optimal foraging strategies by combining different food densities in each area. In other words, this inductive reasoning optimizes strategies and decision-making by deriving the "whole" from samples of the component parts.

Wass et al. (2012) studied a form of inductive reasoning for foraging in mice using a Binary Tree Maze, inspired by procedures developed in human decision analysis for identifying the most efficient strategies to reach a goal. The Binary Tree Maze is a decision tree that bifurcates (at decision points) into branches. Each decision point is a potential goal location, and the end of each branch terminates in two "leaves," each of which also contains potential goal locations, providing (in this example) a total of 14 potential goals (although only a random selection of goals were baited on any particular trial). In Wass' study, the mice's task was to navigate the maze so as to inspect every potential goal for a piece of food. While there are many possible search strategies (or paths) to visit every node in a decision tree, the vast majority of these paths would be inefficient due to unnecessary node crossings (in other words, they would involve unnecessary retracing of a path or crosses of a location that had already been explored). What distinguishes the Binary Tree Maze from a standard maze learning task is that no single path is "best"; many routes are equally efficient, and a mouse might perform errorlessly across trials yet not follow the same route on successive trials. The degree to which a mouse could comprehend the structure of the maze from successive experiences in it and implement that information from its current location is a reflection of inductive reasoning. In the study, Wass et al. found that in their initial exposures to the decision tree maze, the mice's pattern of behavior suggested a disorganized random search. However, within six trials, the patterns of individual animals stabilized and remained stable. At the end of several days of testing, many mice were performing at optimal foraging efficiency, suggesting that the mice quickly came to appreciate the underlying structure of the maze and fix on a strategy for its solution. (However, some mice still performed poorly, which is indicative of wide variability in those mice's inductive reasoning.)

Furthermore, Wass et al. (2012) also determined if mice were relying on rote paths through the maze or whether they were engaging in an active search of the maze (a requisite for inductive reasoning). To make this determination, each mouse was allowed to begin its exploration of the maze, and upon making its first entry into a second level branch, the adjacent branch was blocked by lowering a black guillotine door. Had a mouse been following a rote (but nominally efficient) path through the maze, this manipulation would have disrupted the utilization of that rote path. Even after this, mice were still able to perform at a high level of efficiency.

This process of optimization of search is also seen in animals as evolutionarily distant from mammals as honey bees. Naug and Arathi (2007) investigated possible sampling and decision rules that the foragers use to choose one option over another by presenting foragers with choice tests in a foraging arena. They showed that a large part of the sampling and decision-making process of a foraging honey bee can be explained by decomposing the choice behavior into dichotomous decision points and incorporating the cost of sampling. The results suggest that a honey bee forager, by using a few simple rules as part of a probabilistic inference process, is able to effectively deal with the complex task of successfully exploiting foraging patches that consist of dynamic and multiple options (Naug and Arathi 2007).

## Categorization

When encountering a new object in one's surroundings, the ability to recognize the item as a member of a known category, such as a potential food item or predator, can be crucial for survival. This process involves inductive reasoning given that it requires derivation of general principles from specific, sample observations (extracting the relevant rule out of limited samples and multiple options). Categorization has been well documented empirically, and many animals possess that ability.

In the 1960s, Herrnstein and Loveland (1964) showed that pigeons could learn to peck for

reinforcement whenever pictures of people appeared on a screen and not to peck whenever pictures without people were presented. Many similar demonstrations followed, where birds and mammals were trained to categorize diverse classes of natural items, from trees and water to other animal species (examples in D'Amato and Van Sant 1988; Roberts and Mazmanian 1988). In addition to natural categories, animals have also successfully classified objects that would have no evolutionary significance to them, such as "cars" and "chairs" (Bhatt et al. 1988), ruling out the possibility that categorization is only based on innate concepts.

Some interesting examples help illustrate the case that animals are able to form categories from sampling the environment. A study with chimpanzees tested the animals' abilities to categorize photographs of natural objects (Tanaka 2001). Chimpanzees were initially trained to match different color photographs of familiar objects from four possible categories. In training, all the comparison stimuli were from the same category in one condition and from different categories in another condition. For all subjects, training performance was consistently better for the "different category" than for the "same category" trials. In probe trials after training, the sample and positive comparison stimuli were different items from the same category, and the foils were selected from among the three other test categories. Remarkably, individual performance was above chance in probe trials, suggesting that categorization by chimpanzees may transcend perceptual resemblance. Furthermore, the researchers replicated these same results later using novel stimulus items from the same four categories. This study demonstrates that chimpanzees can group perceptually different exemplars within the same category and suggests that these animals formed conceptual representations of the categories.

In an analogous study, Range et al. (2008) presented dogs with a touch-screen testing procedure, which allowed them to test visual discrimination without the presence of social cueing (social cues from humans are a known to be a big confounding factor in cognitive/behavioral studies with dogs, as they coevolved to be very

sensitive to our cues). They first trained dogs to differentiate between a set of dog pictures and an equally large set of landscape pictures. All subjects learned to discriminate between the two sets and showed successful transfer to novel pictures. Interestingly, presentation of pictures providing contradictory information (novel dog pictures mounted on familiar landscape pictures) did not disrupt performance, which suggests that the dogs made use of a category-based response rule with classification being coupled to category-relevant features (of the dog) rather than to item-specific features (of the background).

Categorization is not only restricted to visual patterns; of course, it is just that those stimuli are easier for humans to study. In an investigation of categorization of song notes in great tits (Weary 1990), the birds were trained first to discriminate between two synthetic song notes. These sounds were models of naturally occurring song notes and differed from one another in five acoustic parameters. Once the birds learnt to discriminate between the two training notes, they were tested with notes that presented all combinations of the five parameters. Responses to these sounds showed that great tits relied almost exclusively on note frequency to form categories; other parameters such as amplitude modulation, frequency modulation, and the interaction between frequency and amplitude were all used to a much lesser extent.

In light of the abovementioned studies, one might wonder: How is inductive reasoning employed during the formation of categories? There are two main theories on how categorization is formed: exemplar theory and prototype theory. For decades, the exemplar theory was dominant in the categorization literature, and it assumes that there is one representational/processing system that serves all needs of categorization. According to the theory, organisms store exemplars as separate, individuated memory traces, refer new items to these stored exemplars, and include them in the category if they are similar enough. However, new research has shown that animals have prior expectations of prototypes (or family resemblance or natural kinds) and exclude exceptional cases (such as a weird looking

predator exemplar from their list of that predator). In other words, inductive reasoning does not do the work from scratch in forming categories as expected by the exemplar theory. Instead, animals use inductive reasoning (among other processes) to infer coherent family resemblance based on prototypical categories already in place. In a review piece, Smith et al. (2016) argue that, based on converging evidence from multiple species, exemplar processing is insufficient to account for the available data on categorization. They claim that prototype averaging might be less effective and create errors of categorization in lab experiments (since in hypothetical situations, you can always imagine weird exemplars) but that in nature prototyping is good enough for a world with so many similarities within categories (most eagles look like eagles, most fruit trees look like fruit trees, etc.), and so being attuned to prototypes would be more advantageous for faster decisions. Or as Smith et al. (2016) writes: “family-resemblance categories dominate. Animals are adept at what they experience and what they need. Their adeptness is neither a coincidence nor a disability” (p. 273).

## Conclusion

Inductive reasoning is present in many different animals, and the multiple ways in which it is expressed show continuities in nature: to different degrees and levels of competence, animals seem to be able to perform causal inference, probabilistic inference, optimizations of strategies based on observation, categorization, etc. Thus, animals are crucial behavioral ambassadors to the study of inductive reasoning in humans.

It is also important to keep in mind that although ubiquitous and important, inductive reasoning in practice can be riddled with problems, even in humans. We are far from the perfect, ideal case from which animals should be compared to, as we, in our daily/ecological (out of the armchair) lives, commit many mistakes in categorization and probabilistic inference (as shown by multiple studies that followed the seminal work of Kahneman and Tversky on how people overlook

statistical variables such as sample size, correlation, and base rate when they solve inductive reasoning problems (Tversky and Kahneman 1974).

## Definition

Inequity aversion in animals is a response to outcomes that are less than, or more than, what a social partner receives.

## Introduction

Humans are an exceptionally cooperative species, regularly engaging in cooperative acts with both related and unrelated individuals. Cooperation in humans has played a fundamental role in the success of our species, yielding unprecedented collective action and a capacity to transmit information through vast social networks, which has provided humans with a key selective advantage that has enabled population growth into even boreal climates (Boyd et al. 2011). In particular, such cooperative tendencies have been vital to our cultural development, facilitating our ability to accumulate complex traits and knowledge over time (cumulative culture), a process that is widely believed to underpin humanity’s extraordinary biological success. Given the selective advantage wide-scale cooperation has conferred to our species, it is important to address why this capability may have evolved and the processes that may underpin it. In this entry, we consider one mechanism that may be essential to maintaining the success of cooperation, inequity aversion.

When considering behaviors, evolutionary scientists typically focus on two features: its function, or why it evolved, and the mechanism(s) by which it operates. Regarding the first of these, the evolutionary pathway that leads to cooperation is relatively well understood. It is typically accounted for by one of the three theories: kin selection, reciprocity, or mutualism. The kin selection account of cooperation is that cooperation can evolve when cooperative acts provide a fitness advantage to related individuals, despite a cost to helper organisms. The account of cooperation that involves direct reciprocity indicates that cooperation can arise when the short-term net losses are outweighed by the long-term benefits of cooperative interactions, often with specific partners. Finally, mutualism describes cooperation that can result in greater immediate payoffs resulting from working together as compared to working alone, without necessarily requiring future interaction. Central to all theories of cooperation is the cost-benefit ratio resulting from collaboration; cooperation requires average individual inclusive fitness to be increased, directly or

indirectly, when cooperating with genetically similar individuals. Herein lies the challenge; for cooperation to evolve, it must provide more benefit than the actor pays in costs.

One way in which this might be done is through a sense of “fairness,” or more precisely, an ability to recognize inequitable outcomes (see Brosnan 2011, for further discussion of the link between inequity aversion and fairness). Specifically, sensitivity to inequity allows organisms to identify when a partner unduly benefits from collaborative interactions versus when partners mutually and fairly benefit. Recognizing when payoffs are equitable or inequitable can inform actors whether it is beneficial to engage in future collaboration or whether it is time to find a new cooperative partner. Indeed, one advantage of having a sense of inequity is that it might allow individuals, in some cooperative contexts, to recognize when they are being cheated by receiving less than they should (rather than receiving nothing at all; Brosnan and Bshary 2016).

In the past few decades, there has been increasing empirical and theoretical attention on whether species recognize inequitable outcomes and how this is (or is not) related to species’ cooperative tendencies. Empirically, researchers have established that many species are averse to inequitable payoffs in at least some contexts. This is described by the term “inequity aversion,” a negative response to an unequal payoff to oneself, relative to others that can take the form of disadvantageous inequity aversion – a response to receiving less than others – or advantageous inequity, a response to receiving more than others (Brosnan 2006). Theoretically, inequity aversion has been hypothesized to constitute one of the mechanisms by which cooperation can be maintained because it allows individuals to judge the value of their partners. Specifically, individuals can judge when they should (i) discontinue interactions with partners that take more than their share of the benefits of cooperation, (ii) replace such unfair partners with more equitable partners, (iii) encourage future interactions with valuable partners by distributing rewards in an equitable manner, and/or (iv) manage their reputation as a fair partner

(e.g., by rejecting unequal but beneficial gains). Such strategies may play an important role in long-term cooperative actions (Brosnan 2011), particularly when unrelated individuals stand to benefit from reciprocity and mutualism. Of course, not all of these benefits will appear in every species, and such behavior could evolve without individuals understanding the function; all that is needed is an evolved negative response to inequitable outcomes that causes individuals to seek out other partners.

In this entry, we take an explicitly evolutionary approach to explore how inequity aversion evolved as an adaption to meet particular environmental and social challenges. We first provide background on the study of inequity aversion in humans, following which we discuss the empirical evidence for inequity aversion in nonhuman species and, in particular, nonhuman primates. We then consider what this tells us about the phylogenetic trajectory of the inequity response. These results indicate that inequity aversion and cooperation coevolved, supporting the argument that inequity aversion is a mechanism to promote successful cooperation. Following this evolutionary view, we look at the degree to which inequity may impact cooperation between individual organisms. Inequity does lead to a breakdown in cooperation, again indicating the degree to which inequity responses are important in cooperation. We end with a consideration of how inequity is related to the human sense of fairness and to what degree studying responses to inequity in nonhuman species can help us understand the evolution of our sense of fairness.

## **The Study of Inequity Aversion in Humans**

One challenge to an evolutionary approach to fairness is that fairness is a social ideal, and it is impossible to study ideals in nonverbal species. Therefore, in order to study this empirically, researchers have operationalized the sense of fairness as an ability to recognize disadvantageous and advantageous outcomes relative to those of a partner. One way researchers have empirically

approached this question has been to examine the choices participants make when they are faced with allocating resources between themselves and a partner. Various scenarios, or “games,” borrowed from the field of economics have been used to investigate the contexts in which humans care about equity. In one such game, called the “dictator game,” a resource (i.e., money) is provisioned to an individual (the proposer) who decides how to divide it between themselves and a “recipient.” In the dictator game, the recipient plays a passive role and has no option to influence the proposer’s offer. Thus, the proposer can share resources at a cost (reduce advantageous inequity or even create disadvantageous inequity) or monopolize resources (maximize advantageous inequity). As the partner does not have a say in the distribution, a situation is created in which selfish behavior pays. This setup has been informative for establishing whether humans make “fair” offers when there is no opportunity for a partner to encourage fairness by reciprocity or recourse.

Dictator games have been played with children and adults of different societies, yielding some interesting developmental and cultural differences. In children, younger individuals act selfishly, keeping all, or the majority, of rewards (e.g., Gummerum et al. 2010). This picture begins to change at around the age of 5, with a developmental shift toward acting more fairly, and children will often begin to distribute the rewards equally. This, and similar research, supports the proposition that children begin life acting in a rather self-centered manner before more egalitarian tendencies begin to set in at around 5–7 years of age. Turning to adults, the typical amount allotted to a partner in dictator games averages around 20% (Forsythe et al. 1994) suggesting that, when a cost is involved and repercussions are absent, humans do not maximize their absolute gains but they are also not perfectly fair, either; instead, they make non-zero but nonetheless inequitable offers that favor themselves.

Comparing the dictator game to the “ultimatum” game shows that contextual features can influence how fairly humans act toward others. The ultimatum game mirrors the dictator game,

with the exception that the recipient can reject the proposed reward allocation, in which case both players receive nothing. This is both a form of punishment and an inequity response (although rejecting means that the recipient now ends up with absolutely less than they could have had, the outcome is relatively equal). In this context, average offers made in Western adults increase to approximately 30–40% (Camerer and Thaler 1995). This indicates that when proposers can lose resources, proposals become more equitable, albeit typically still not equal. The ultimatum game mimics situations in which individuals, at a cost, can defect from partners that cheat or unduly benefit, a situation that encourages equity. That human fairness judgments are linked to contextual and social factors is further highlighted by cross-cultural studies. Interestingly, economic games, such as the dictator and ultimatum games, played with different societies, reveal large between-group variations in the proposals humans make (Henrich et al. 2004). Such findings suggest that the human notion of fairness is very sensitive to differences in social and ecological environment as well. In particular, as is expected if the hypothesized link between fairness and cooperation is correct, more generous offers are proposed in societies that rely heavily on cooperation and trade (Henrich et al. 2004).

Researchers have also made use of the “inequity game” to explore humans’ reactions to inequitable outcomes. In this game, two participants take the role of the “actor” and “recipient” and the experimenter provisions either equitable or inequitable rewards. The actor then makes a decision of whether to accept or reject the reward distribution, the latter of which results in both participants receiving nothing. By including rewards that benefit and disadvantage actors relative to the partner, investigators can establish whether subjects may be averse to advantageous, disadvantageous, or both forms of inequity. The inequity game was recently employed in a large-scale study encompassing seven different societies and over 800 pairs of children, finding that children in all populations tested rejected disadvantageous rewards. Disadvantageous inequity aversion appeared around the age of 4 but with variation in

the age of onset across the populations (Blake et al. 2015). Rejection of advantageous rewards, in contrast, occurred only in some societies and at a later age. Importantly, such findings have helped to disentangle advantageous from disadvantageous inequity and emphasize that a self-serving bias to avoid disadvantageous outcomes appears to be a universal human trait, whereas aversion to advantageous outcomes appears to be influenced by society and culture.

Researchers have hypothesized that inequity responses evolved in tandem with cooperation (Brosnan 2006, 2011; Fehr and Schmidt 1999). In particular, inequity is purported to act as a mechanism to compare one's own outcome to those of others following collaborative effort. Experimental support for this has been emerging in the nonhuman literature (discussed below) but several lines of evidence link fairness decisions to cooperation in the human literature as well, often indicting that cooperation strengthens subjects' motivations for fair payoffs.

Investigators have exposed children to experimental cooperation tasks very similar to those run with nonhuman primates, allowing some direct comparisons to be made. In one such example, Warneken et al. (2011) set 3-year-old children the task of working together to gain otherwise unavailable rewards that were either separated into two distributed piles, and thus could not be easily monopolized by one child, or were clumped into a single pile that could be easily monopolized. Importantly, children as young as 3 years of age mostly split the resources evenly in the clumped resource condition, suggesting children knew what was "fair." This result contrasts with contexts that do not require children to engage in joint action, which reveal more selfish intentions in children of this age (e.g., in the dictator game: Gummerum et al. 2010). If we compare this to cooperative studies with chimpanzees (*Pan troglodytes*), we find high levels of resource monopolization and a break down in collaboration in chimpanzees, but not children (Hare et al. 2007). Bonobos (*Pan paniscus*), argued to be more socially tolerant than chimpanzees, tested on this paradigm behaved more similarly to humans, outperforming chimpanzees in the clumped

resource condition. That being said, more recently, chimpanzees have been shown to share food more often and show greater tolerance in this context than bonobos, leaving open the question of how our closest evolutionary ancestors shared food (Jaeggi et al. 2010). Nevertheless, such findings linking tolerance and cooperation have led researchers to hypothesize that social tolerance over resources plays an important role in mediating cooperation and that the low-tolerance levels observed in some species is a major constraint on their cooperative tendencies. Thus, ensuring equity, either actively by sharing or through high social tolerance for co-feeding, may be a key factor in sustaining collaboration, whereas disadvantageous inequity aversion, coupled with competitive tendencies, may limit such opportunities. This supports the prediction that cooperation may be maintained over the long term by distributing rewards in an equitable manner or choosing to work with partners who do so.

Similar cooperation studies show that by the age of 3, children will correct resource inequity after working together, sharing resources to a greater extent after such collaboration than when working in parallel or when simply gifted with resources (Hamann et al. 2011). Children are also more likely to share rewards evenly with those who collaborate than with free riders (Melis et al. 2013). These findings suggest that children engage in equitable reward distribution based on collaboration and work effort (equity) rather than simply ensuring equality irrespective of collaboration. Comparative work with chimpanzees shows no such flexible sharing according to whether others collaborate or not, indicating a potentially important species difference (Hamann et al. 2011). In addition to correcting resource inequities following cooperation, humans also anticipate who may serve as good collaborators. For example, at 15 months of age, children already select partners that are fair over unfair ones (Burns and Sommerville 2014). By adulthood, cooperative partners are selected according to how generous they are, they will act more generously when observed and will even compete to be more generous than each other when future cooperation can lead to

personal gain (Barclay and Willer 2007). Of course, individuals need not always be aware of the future benefit of selecting fair over unfair partners (e.g., 15 month olds almost certainly do not understand this) nor need they understand how such strategies work. Instead, attraction to or a preference for fair or generous partners (in combination with a preference to end unfair cooperative relationships) could maintain selectivity for partners that are likely to provide equal or beneficial gains in future collaborations.

The study of inequity aversion in humans has taken many forms, using tasks, joint activities, games, and vignettes, with various dependent measures ranging from self-reports or emotional reactions to active resource allocations and the rejection of absolute gains if they lead to relative inequality. Key findings have emerged that provide insight into which facets of fairness children may be biologically predisposed to pay attention to and which may require some social experience and culture. Concerning the former, that children from an early age (around 3–4 years old), and from various cultures, respond to disadvantageous inequity across multiple experimental contexts, suggests that disadvantageous inequity aversion is a robust response; humans, it seems, do not like to receive less than partners and are willing to pay a price to avoid such circumstances. On the other hand, an aversion to receiving more than partners – advantageous inequity – follows a different developmental trajectory, appearing later in development (around the age of 8 in Western populations) and is subject to strong cultural influence (Blake et al. 2015). Equity choices also depend upon contextual factors, suggesting that fair behavior is not employed indiscriminately. Rather, sharing depends upon factors such as who the partner is and how much effort they devoted to a task (cooperation) and whether the partner can influence payoffs (e.g., ultimatum games) or not (e.g., dictator games). Such selectivity begins with choosing with whom we prefer to interact or cooperate. This indicates that our treatment by others (e.g., fair or unfair) influences whether we choose to engage with them or select someone else with whom to work.

## The Study of Inequity Aversion in Nonhumans

Humans show strong responses to inequity, but what about other species? Evidence accumulated over the past few decades shows that some other species react negatively to receiving a less desirable outcome than their partners. In a typical test of inequity aversion in nonhuman species, two partnered individuals each complete a task to receive a reward. The task is completed sequentially – with each individual taking turns – and the rewards provisioned to each partner are either the same (equity condition) or different (inequity condition). If subjects are inequity averse, a pronounced reaction should occur in the inequity condition relative to the equity condition. While different tasks have been used to study inequity aversion (and in some cases, no task at all), the majority of studies have employed an exchange paradigm in which subjects take, and then return, an object (“token”) to the experimenter for a food reward, essentially bartering it. This method was originally conceived by Brosnan and de Waal (2003) and applied to brown capuchin monkeys (*Cebus [Sapajus] apella*). The authors documented higher levels of rejection (unwillingness to exchange a token or consume a reward) in individuals that were offered cucumber (a less preferred food reward) following their partner’s receipt of grape (a favored food) as compared to their rejection rate in the baseline equity condition, in which both exchanged for cucumbers. The authors interpreted this result as reflecting a response to inequitable outcomes based on social comparison, that is, “inequity” based on the reward disparity between oneself and others, rather than a reaction to personally observed or experienced reward differences.

This interpretation did not go unchallenged. Two alternative explanations to the authors’ conclusion were based on nonsocial responses to unequal “pay.” First was “food frustration effects” in which the mere presence of a better reward could enhance rejections if the favored food was present in the inequity, but not in the equity, condition. The second challenge was the potential

frustration brought on by a violation of an expectation to receive a favored, and previously experienced, food when the subject instead receives a less preferred food (i.e., an expectation based on past reward history). More recent studies of inequity, however, have controlled for these alternative explanations by ensuring that both favored and non-preferred foods are visible in all study conditions and by the inclusion of controls for potential frustration, typically with a condition in which subjects are shown a favored food before offering a less preferred food, and by randomizing the order in which conditions are presented. Even with these controls, social comparison, or inequity aversion, still occurs. This suggests that refusals are not simply (or only) due to seeing better rewards or any potential frustration caused by expecting a better reward than is received.

Brosnan and de Waal's initial study of inequity aversion in capuchin monkeys paved the way for new research exploring such capabilities across the primate order and, in a recently emerging trend, non-primate species. At least 30 studies have now been published, and these find substantial variation across species and contexts (see Brosnan and de Waal (2014) for a table including all studies published to that date). Here we briefly summarize this research, focusing on what species show a response to social inequity and, where possible, the influence of procedural and contextual variables on the manifestation of the inequity response.

## The Phylogeny of Inequity Aversion

Among the great apes, chimpanzees are the most studied species. Chimpanzees generally show some degree of inequity aversion, much like the brown capuchin monkeys (see Brosnan and de Waal 2014; Price and Brosnan 2012). However, they are notable because their responses are subject to high levels of group and individual variation that has been linked to various social and personal factors, not always in consistent ways. Investigations using very similar protocols have shown that dominance, social affiliation, and gender can all influence inequity responses in

some, but not all, situations. Brosnan and colleagues, for example, have documented a stronger response in dominant individuals when they were undercompensated relative to a lower-ranking partner, but this dominance effect was not found in other studies (see Price and Brosnan 2012 for a review of these data). Similarly, there have been cases of chimpanzees with close social ties (i.e., housed together for long periods) being less responsive to a partner being overcompensated as compared to chimpanzees that were housed together for much shorter periods, although again, there have also been studies in which no such variation was seen. Such inconsistencies have encouraged researchers to search for individual differences that may account for some of this variation. Personality, for example, was recently found to correlate with social inequity responses, although it seems likely that relationship quality, which influences which individuals will voluntarily pair together for the tasks themselves, affects their responses as well (Brosnan et al. 2015).

Other factors not yet considered likely also underpin this variation. For example, the social configuration and tolerance of partnered animals may influence responses to inequity (reviewed in Price and Brosnan 2012), as could variation in subjects' daily food intake and any social change that may occur in the group at the time of testing. There may also be interactions between factors. For example, dominant individuals may show strong inequity responses simply because they are more satiated at the time of testing, through prior resource monopolization, relative to less dominant individuals. Satiation likely increases the likelihood of the costly behavior of forgoing an immediate, less preferred food in inequity conditions. Furthermore, dominants may be used to receiving the best foods from humans, strengthening potential inequity responses. Depending upon one's group, and indeed housing facility, dominant individuals' propensity to monopolize food could vary, with implications for the food refusal rates. One open question, then, is whether inequity aversion in the context of food rewards is an artifact of captivity, as forgoing an immediate reward incurs little cost where there is reliable, and sufficient, food provisioning. This question

requires investigation in natural populations and could be examined by documenting participation levels in coordinated activities following equitable and inequitable gains, for instance, looking at whether coordinated hunt participation lowers following disadvantageous inequitable food returns and exploring how participation may interact with food scarcity. It will also be important to determine in which other contexts inequity may influence behavior in natural conditions, particularly outside of the context of food.

Turning to the other great apes, comparatively less work has been conducted on inequity aversion. We know nothing of gorillas' (*Gorilla spp.*) capabilities, except that they do not respond to inequity when rewards are "gifted" by the experimenter (i.e., in the absence of a task; see Brosnan and de Waal 2014). However, no response in a free-feeding context is common across species. In every primate species in which inequity has been documented, subjects only respond negatively when the food rewards are received subsequent to completing some sort of task; when rewards are handed out "for free," the same subjects do not respond negatively even when they are unequal. We know little more about the other great apes, with only one published exchange study focusing on bonobos and two on orangutans (Bräuer et al. 2009; Brosnan et al. 2011). For bonobos, evidence points toward some presence of inequity aversion; however, as only five subjects have been tested, the results are inconclusive (Bräuer et al. 2009). The two studies that have examined whether orangutans respond to disadvantageous inequity document no such trend in socially housed orangutans (Bräuer et al. 2009; Brosnan et al. 2011). This is interesting, should it hold, as orangutans are among the least social primates, particularly in comparison to other great apes, and rarely cooperate in the wild. However, given this paucity of data in bonobos and gorillas, it is difficult to determine how inequity responses may have evolved among the apes.

Experimental studies of inequity have also focused on monkeys, including macaques (*Macaca spp.*), capuchins (*Cebus spp.*), squirrel monkeys (*Saimiri spp.*), owl monkeys (*Aotus spp.*), marmosets (*Callithrix spp.*), and tamarins

(*Saguinus oedipus*; see Brosnan and de Waal 2014 for a review of this literature, including citations for studies on each species). Capuchin monkeys, like chimpanzees, have been highly studied, and also like chimpanzees, show variation in their responses, with some studies finding evidence of inequity aversion while others have not. Interestingly, among the other New World monkeys that have been tested (common marmosets, owl monkeys, squirrel monkeys, and tamarins), no species has been shown to respond to disadvantageous inequity. However, much like in the great apes, the focus primarily on one species – capuchins – with very little data available concerning other New World monkeys makes it premature to conclude that other New World species lack a response to inequity, particularly given the variation in individuals' responses in the best studied species. The situation is even less clear in Old World monkeys, for which only macaques have been tested. Both species tested thus far (rhesus and long-tailed macaques) do respond negatively to social contrast. More recently, researchers have studied non-primate species, and initial data indicate that domestic dogs, rats, and corvids respond to the presence of, or the potential for, inequity (reviewed in Brosnan and de Waal 2014).

Considering variability within species, one factor proposed to explain such discrepancies, at least in part, is the experimental procedures employed. The combination of work effort provided by a task and subject's proximity to their partner appear to be important for the expression of inequity aversion, with studies that have distant partners and/or no task generally reporting a lack of a response to inequity, even in species and groups that show inequity in other contexts (Brosnan and de Waal 2014). Other factors, such as the relative value of the rewards may also impact inequity aversion; for instance, the preference discrepancy between some food pairings (e.g., pine nuts versus sunflower seeds) may differ to those used in other studies (e.g., cucumber versus grape). While the relative value of foods is always established *within* studies, these values still differ *between* studies, and recent research in capuchins shows that relative food values strongly impact inequity responses (Talbot et al. 2017).

Finally, social and individual differences impact inequity aversion in chimpanzees, which may also play a role in other species' unfairness judgments. For example, the relatedness of subjects and partners are rarely reported but could have a profound effect on whether animals are inequity averse or not. Individuals' propensity to use social over personal information may also determine responses to inequity. Many animals collect both kinds of information but are reported to prioritize personal over social information (Rieucan and Giraldeau 2011), meaning that animals may not always attend to social contrasts.

Considering the variability across species, what does this phylogenetic dispersal of inequity aversion tell us about the evolution of disadvantageous inequity aversion? Most apparent is the inconsistent distribution of disadvantageous inequity aversion across the primate order and its presence in diverse taxa both within the primates and beyond (e.g., corvids and rats). From this, it is evident that convergent evolution is at play (Brosnan 2011); disadvantageous inequity has evolved independently in various organisms, likely in response to similar ecological and/or social niches. Such pressures have been hypothesized to include species' sociality and degree of cooperation with non-kin. Sociality alone does not appear critical here as some gregarious species, living in large social groups, are nonetheless insensitive to inequity (e.g., squirrel monkeys). Instead, recent theory has favored a link between inequity aversion and cooperation with non-kin; of course, regular exposure to non-kin relates to species sociality/social structure, but the cooperation component seems to be important. Wild chimpanzees engage in coordinated hunts, territory defense, and coalitions, suggesting cooperation or at least behavioral coordination between group members. Likewise, the social behavior of capuchins and macaques hints at cooperation with non-kin. A number of experimental studies also show a degree of cooperation in these species, and even that inequitable outcomes will disrupt cooperation, providing further evidence for this link.

In considering the relationship between inequity aversion and cooperation, factors that complicate the picture should be noted. First,

cooperation between non-kin alone does not appear sufficient for the emergence of inequity aversion. Cooperative breeders (marmosets and tamarins), species in which both parents and, sometimes, older offspring work together to raise infants, show no reaction to inequity. This may be due to the high level of interdependence between males and females that renders a negative response to inequitable outcomes more costly than beneficial (i.e., the cost of finding a new mate, and risking losing one's current reproductive investment, is higher than the cost of inequity in most contexts; Brosnan 2011). One caveat here is whether cooperative breeders may be socially tolerant in some, but not other, situations. Cooperative breeders, for example, may be sensitive to inequitable contributions in work effort but tolerant of inequitable food returns. Second, as many studies have been conducted in highly controlled laboratory contexts, the extent to which the apparent sensitivity to inequitable outcomes generalizes to the natural environment remains unknown. Third, given the large variation in the inequity response documented within those species most studied (chimpanzees and capuchins), caution must be used when assuming an absence of inequity aversion in species based on just one or two studies. Finally, it is important to keep in mind that ecologically valid measurements of cooperation in natural populations could have more relevance to interpreting the possible relationship between inequity aversion and cooperation than those derived from captive studies, which may be more artificial. This is highlighted by orangutans, a semi-solitary species, that in two independent studies did not respond to inequity nor do they show high cooperative tendencies in the wild, yet they will work together to gain a reward in a captive setting, cooperating much like chimpanzees and capuchins (Chalmeau et al. 1997).

Overall, while it is currently the best-supported hypothesis, additional data are required to test the hypothesis that inequity aversion and cooperation coevolved. In particular, contrasts between closely related species known to cooperate with non-kin in the wild and those that do not, and social versus solitary species, would be useful in this regard. Another means to examine the link

between cooperation and inequity aversion has been to establish whether inequitable outcomes directly influence the success of cooperation. To do so requires studies in which resource distributions can be manipulated or controlled; thus, while ecological valid measurements in the wild are important, the available evidence derived from controlled experimental tests of cooperation must also be considered.

### The Influence of Inequity on Cooperation in Nonhumans

As discussed above, inequity aversion is hypothesized to help maintain cooperation by enabling organisms to do one or more of the following: (i) disengage from collaborating with those from whom they receive unfair returns, (ii) encourage more equitable future gains by choosing equitable partners, (iii) encourage future cooperation by distributing rewards in an equitable manner, and (iv) manage their reputation as a fair partner by rejecting unequal but beneficial gains. We have previously described how humans readily distribute rewards equitably following collaboration, select fair or generous partners, and will sometimes reject advantageous inequitable rewards. In this section, we consider whether inequity aversion constitutes a key mechanism supporting long-term cooperation in nonhumans by focusing on each of these predictions.

Studies of inequity aversion show that some individuals are less likely to participate in tasks when they receive unfavorable outcomes relative to a social partner. Inequity tasks, however, do not require cooperation between partners, which is a key component of this hypothesis. As a result, additional work has been done focusing explicitly on cooperation and reciprocity. In one such study, Brosnan et al. (2006) designed methods to directly test the assumption that unequal rewards influence levels of cooperation. Pairs of capuchins could perform a joint action (pull in a counterweighted tray) to gain rewards that were either equitable or inequitable. Key to this study was that participants, who were co-housed in the same enclosure, had to decide who worked for each reward. Thus,

conflict could arise over the unequal resources. The authors found that when a dominant partner “unfairly” benefited by monopolizing the better reward, cooperation tended to break down. Indeed, cooperation rates when partners took turns in gaining the better reward were two to three times higher than when dominants monopolized the better outcomes, and cooperation with unfair partners broke down even in control tests in which rewards were equal. What this research suggests is that capuchins will cooperate over long periods even when short-term rewards are unequal as long as each partner is willing to “play fair” over the long term, yielding (roughly) equitable gains to both partners overall.

Similar findings have been documented in chimpanzees; they select partners based on their previous history of tolerant sharing (Melis et al. 2006), reduce their cooperation when rewards can be monopolized by dominant individuals (Hare et al. 2007), and, when not cooperating with kin, prefer to work with partners of similar rank, who are presumably more socially tolerant partners (Suchak et al. 2014). These findings indicate that some primates remedy inequity through partner selectivity, that is, by not working collaboratively when resources are or can be monopolized and/or by taking turns gaining the beneficial but inequitable outcome of collaboration. Thus, there is some support for the predictions that inequity aversion may result in (i) leaving collaborators that take more than their share, (ii) using partner choice to manage future gains, and possibly even (iii) distributing rewards in an equitable manner to promote cooperation between individuals (i.e., capuchins taking turns to gain the best reward).

The last prediction indicates that inequity aversion may aid cooperation when individuals reject inequitable, but beneficial, outcomes (i.e., advantageous inequity aversion), perhaps encouraging future reciprocity or gaining a good reputation to attract future partners by establishing oneself as a fair partner. Interestingly, while in no study to date have monkeys minded options that reward themselves more than a partner, one study documented chimpanzees rejecting a preferred food when a partner received a non-preferred food (i.e., advantageous inequity aversion), albeit at a *much* lower

rate than they rejected a less preferred food when a partner received a more preferred food (reviewed in Brosnan and de Waal 2014).

Researchers have also tested nonhuman primates on the ultimatum game. As in the human ultimatum game described above, two individuals are assigned the “proposer” and “responder” roles. The proposer offers some of the resources to the responder, who can accept the offer, in which case each receives the rewards set out by the proposer, or reject the offer, in which case neither receives anything. Interestingly, as would be predicted by game theory, chimpanzees appear to accept any non-zero reward offers, suggesting they are rational maximizers (Jensen et al. 2007; Proctor et al. 2013). This is unlike humans, who will reject offers below around 20% of the endowment. Chimpanzee proposers, on the other hand, make both fair (Proctor et al. 2013) and selfish offers (Jensen et al. 2007). In one study, proposers did not make the fair offer to their partners (Jensen et al. 2007); however, these chimpanzees also showed the costly behavior of delivering zero rewards to their partner, which had high rejection rates (44%), despite the availability of a second self-serving option that was only rejected by their partners 14% of the time. This, coupled with responders’ rejection of zero offers on only 44% of trials, suggests that the chimpanzees only had a limited understanding of this task. In a more recent version, chimpanzees did prefer fair offers in the ultimatum game more so than in a preference test that was similar to a dictator game (Proctor et al. 2013). Key to this study was that fair reward options were favored only when partner chimpanzees had recourse to reject offers (i.e., the ultimatum condition), whereas selfish offers were favored when partners had no such ability (i.e., the dictator analogue), suggesting that the chimpanzees understood the procedure. Indeed, the lack of refusals by the responder may be logical in a repeated game with a known partner; rather than rejecting and ending the relationship, chimpanzees could protest and encourage the proposers to choose the more equal outcome. Therefore, even though the recipient will receive less on a few occasions, overall it is worth their while to continue the interaction (Proctor et al. 2013).

Further indication that chimpanzees may be sensitive to gaining more than conspecifics is a finding that chimpanzees, in a group situation, counterintuitively opt to follow the low-paying behavior of a dominant chimpanzee, despite the presence of a better-paying alternative (Hopper et al. 2011). The authors interpreted this as chimpanzees “conformity” to the low-paying behavior of the dominant chimpanzee (Hopper et al. 2011). An alternative explanation is that the selection of the low-paying behavior could be due to an aversion to advantageous inequity: perhaps the costs of receiving more than the model were too high to make it worthwhile to use the better option.

Research over the past two decades highlights the link between cooperation and inequity aversion. Further research is required to tease apart in which situations primates are indifferent versus being sensitive to others’ payoffs and how this is mediated by opportunities to cooperate, reciprocate rewards, and, in some cases, punish others or manage one’s reputation. Nonetheless, several studies now support the hypotheses that primates manage cooperation by leaving unfair collaborations and by being selective about which partners they choose. Less clear is whether nonhuman primates actively distribute rewards fairly (as could be the case of capuchins taking turns to gain the best reward) and, related to this, the degree to which any nonhuman species routinely shows refusal of unfair but beneficial personal gains. These qualities might constitute notable species differences between humans and other primates, as may other cognitive abilities (i.e., inhibiting one’s desire to accept the better reward or planning for future interactions).

## The Evolution of Fairness

Inequity aversion has been found in diverse species, including rats, dogs and wolves, some birds, and primates. The comparative literature has provided important insights into the evolution of the human sense of fairness. Knowing that inequity aversion has evolved in these diverse taxa

indicates that convergence, rather than evolution through common descent, has been at play. Researchers have also now established that a sense of fairness can take different forms, and while disadvantageous inequity appears more widespread across taxa, advantageous inequity aversion is extremely rare. Indeed, even among humans, disadvantageous inequity aversion appears to be both more widespread and to develop at an earlier age, indicating a strong biological influence. Species found to have both forms of inequity aversion come close to having the “complete” sense of fairness seen in humans. Of course, humans’ sense of fairness entails other aspects that are likely not present in other species, such as explicit group norms of behavior. How humans’ advanced sense of fairness, which requires advanced cognition and emotional control, arose during the course of our evolution remains a significant question for science. Nonetheless, one explanation consistent with the current evidence is that fairness coevolved with cooperation with non-kin, and functions to help individuals maintain beneficial cooperative relationships. It is clear that individuals benefit from leaving partnerships in which they routinely get less than the partner, but they may also benefit from declining an unfair advantage. By paying the short-term costs of rejecting an unfairly advantageous outcome, individuals signal to their partner (and potentially to others) that they value the partner. If they can ameliorate their partner’s frustration, the long-term relationship can continue (see Brosnan and de Waal 2014). Humans, with our exceptional abilities at delay of gratification and planning for the future, inhibition, and understanding of others’ thoughts and feelings (i.e., theory of mind), were able to take these roots and develop the full-blow sense of fairness seen in humans today.

## Infanticide

Ming Fei Li

Department of Anthropology, University of Toronto, Toronto, ON, Canada

## Definition

The act of killing a young offspring who is usually dependent and vulnerable.

## Introduction

Across the animal kingdom, there are cases of infants being targeted for murder by parents or unrelated individuals. Although the killing of a young seems counterintuitive since it puts an end to the genetic lineage, there might be an evolutionary explanation for this behavior in animals. Infanticide is costly, particularly for the parent that has invested greatly into rearing and taking care of their offspring, and of course, it is fatal for the infant. This article will go over the main hypotheses for why infanticide occurs among animals and highlight some counterstrategies that have evolved to prevent infanticide.

## Hypotheses for the Role of Infanticide

One explanation for infanticide is that it is non-adaptive, meaning it is not providing any benefits to the perpetrator (Ebensperger 1998). Infanticide could occur when group members are being overly aggressive and since infants are less able to defend themselves; they are more likely to be injured or killed. For example, during intense male-male competition for mating access, infants might accidentally get caught in harm's way and die. In other words, perpetrators are not purposefully killing infants for fitness gains; therefore, infanticide is nonadaptive. Although there are always cases of accidental deaths in the wild, the prevalence and pattern of infanticide suggest that it is not simply a "one-off" phenomenon but serves an evolutionary purpose. Therefore, the next three hypotheses offer adaptive explanations for infanticide.

The predation hypothesis states that infants are killed to provide nutritional gains; infants are killed and then consumed as a food source (Hrdy 1979). This hypothesis could be used to explain cases of interspecific and nonparental infanticide where predators choose infants as easy targets to capture and feed on. It has been found that the frequency of infanticide and cannibalism increase when food is scarce, thus further supporting the predation hypothesis. If the perpetrators are the parents, then the benefits gained from consuming the infant should outweigh the costs of losing an offspring for this behavior to persist.

The resource competition hypothesis states that infants are killed to eliminate a competitor for access to physical resources such as food and space (Hrdy 1979). By killing an infant, the perpetrator can then have more of these resources for themselves and/or their own offspring. Parental infanticide can be a strategy by the parent to downsize their litter so there is less competition for limited resources and a greater investment per infant – quality over quantity. There is more support for the resource competition hypothesis in cases of nonparental infanticide. For example, in a coterie of black-tailed prairie dogs (*Cynomys ludovicianus*), lactating females were the most common perpetrators of infanticide and their

victims were the offspring of close kin (Hoogland 1985). Infanticide was not always followed by cannibalism, so this does not satisfy the predation hypothesis, but the resource competition hypothesis offers a compelling explanation. Lactating females are getting rid of future competitors so that both her and her offspring will have more access to resources. The most common examples of infanticide in mammalian species are when invading males kill unrelated infants in the group. Invading males are removing competitors from the group so that they will not compete for resources or challenge their dominance in the future.

Hrdy (1979) proposed the sexual selection hypothesis to justify the sex-biased occurrences of infanticide since the majority of observed cases were male-inflicted. This hypothesis states that infanticide is a male adaptive strategy. Males kill unrelated infants to eliminate other males' progeny and potential mating competitors and by doing so, increase their own chances of reproductive success. Indeed, most cases of infanticide are nonparental; the perpetrator is targeting infants that are not likely to be related to them. In addition, the interbirth interval of females often gets shortened if she loses her offspring, which makes her sexually receptive to mate again. In Hanuman langurs (*Presbytis entellus*), infanticide was most common after the resident alpha male had been ousted by a new male (Borries and Koenig 2000). In addition, females that just lost their infants had shorter interbirth intervals and the perpetrator subsequently sired their next infants (Borries and Koenig 2000). This example demonstrates that there is a reproductive advantage for the males to kill unrelated infants, thus, adding support for the sexual selection hypothesis. Phylogenetic analyses of mammalian species have shown that infanticide is more likely to occur in species where females are able to breed throughout the year (Lukas and Huchard 2014). Selection pressure favors infanticide only when the mother is able to be sexually receptive following the infant's death, therefore, the male perpetrator is gaining reproductive advantage.

In mammals especially, the female has invested tremendous time and energy into rearing and

caring for her offspring, which makes infanticide extremely costly. Therefore, a sexual conflict arises whereby males want to increase their reproductive fitness by killing unrelated infants while females want to increase their reproductive fitness by keeping their infants alive. This conflict of interest creates an evolutionary arms race between the sexes which result in the development of counterstrategies.

## Counterstrategies to Infanticide

One female counterstrategy to prevent infanticide is to actively defend her infants from male aggressors. Oftentimes, the male that sired the infant will also defend against the attacker since it is in his best interest to protect his young. Females will sometimes join together to attack infanticidal males, and this has proven to be successful in lions (*Panthera leo*) (Packer and Pusey 1983). There is strength in numbers and one benefit of forming social bonds in a group is that members can come to each other's defense during times of need. A second counterstrategy is to avoid infanticidal males. As discussed above, infanticide is common following the takeover of a group by a new male. During these takeovers, mothers can leave the group with their offspring, either temporarily or permanently. Once her infants have become independent, then the mother may choose to return to the group where risk of death for her offspring has decreased. Another female counterstrategy is sexual promiscuity, where a female will mate with multiple males to confuse paternity and lower the chances of her infant being targeted (Hrdy 1979). Since any one of the males she mated with could have sired the offspring, they should not risk killing their own infant. Females sometimes display "pseudo-estrous" where they continue to mate even after conception. This behavior has no obvious benefits to the female other than to confuse paternity. Finally, the last counterstrategy is actually an effort on the infant's part to prevent infanticide, and that is accelerated infant development. Ursine colobus infants (*Colobus vellerosus*) have a distinct white natal coat that makes them extremely

susceptible targets by infanticidal males. Male infants, who are targeted more often since they pose a greater threat as future competitors, transitioned from white to grey earlier than female infants (Bădescu et al. 2016). Accelerated infant development may have evolved as a counterstrategy to infanticide.

## Conclusion

Infanticide could be a nonadaptive behavior with no benefits for the individuals involved. However, there is strong support for adaptive explanations of infanticide, such as for nutritional gains, less resource competition, and increased male reproductive success. Counterstrategies have also evolved to prevent infanticide, such as parental defence, avoidance of infanticidal males, female sexual promiscuity, and accelerated infant development. There is evidence to support and refute each of the hypotheses presented; nevertheless, it is imperative to continue to investigate why this behavior has persisted in a variety of animal taxa.

## Synonyms

[Intragroup](#); [Within-group](#)

## Definition

An in-group is a social category or group with which one strongly identifies with (Kurylo 2013, p. 141).

## Introduction

A well-studied area within animal cognition is that of in-group biases, or as it is sometimes called,

favoritism. These biases can be described as within-group members cooperating more strongly together than with outgroup members (Masuda and Fu 2015). This affects behavior in several species of animals, including birds, chimpanzees, and fish (Campbell and de Waal 2011; Gallup et al. 2017; Palagi et al. 2009). Three of the most common in-group behaviors are affiliation, aggression, and cooperation. These behaviors are often affected by other behaviors and situations that occur both inside and outside of the group (Asensio et al. 2008; Boesch 1994; Brintjes et al. 2016; Heinsohn and Packer 1995; Radford 2011; Risenhoover and Bailey 1985; Southwick 1967).

Affiliative behaviors altered by cognitive biases include grooming, stretching, and yawning (Campbell and de Waal 2011; Gallup et al. 2017; Palagi et al. 2009). Chimpanzees, baboons, and birds will often increase these behaviors when exposed to members of their own in-group through videos or in physical proximity. For example, birds exhibit increased stretching when around other group members. In chimpanzees, contagious yawns are more frequent when they see a member from their own group. For baboons, contagious yawning and grooming increase when the animals are socially near their own group. Grooming is also considered an affiliative behavior among species of birds when an outgroup threat is present (Brintjes et al. 2016; Radford 2011). In both cases, whether the outgroup threat is a physical altercation or just a threat, affiliation will increase. In birds, grooming of another in-group member increases after an out-group threat. The grooming will also occur for longer periods of time if the out-group threat is located within close proximity. In fish, affiliative behaviors also occur, but not grooming. Instead, soft touching and parallel swimming occur more frequently after a physical altercation with an outgroup member.

Aggression is frequently seen among group members, as well. The size of the group can determine whether the aggressive behavior increases or decreases. Studies examining the relationship between group size and aggression all agree the two variables are related, but how they are related differs (Asensio et al. 2008; Risenhoover and

Bailey 1985). In mountain goats, aggression tends to decrease when the animal group increases in size. However, in spider monkeys, aggressive behavior will increase as the group becomes larger. Aggression is also more frequent when there are new members introduced into the group. This behavior can be exhibited in both rhesus monkeys and spider monkeys. These new members will initiate aggressive behavior in members because of their group status (Asensio et al. 2008; Southwick 1967).

Finally, group members participate in situation-specific cooperative behaviors with their group members. Specifically, cooperation affects tolerance to group members with regard to hunting and territorial defense (Boesch 1994; Heinsohn and Packer 1995). Lions and chimpanzees surprisingly tolerate members who do not cooperate with others in the group. In lions, those who do not take part in the cooperation of defending territory are not always punished by those who do. The same behavior can be exhibited in chimpanzees when certain members do not participate in hunting for food. Group members do not always receive consequences from others when they eat the food without hunting. Specifically, chimpanzees who participate in the hunting will tolerate these “cheaters” more if they are related to them. This shows how kinship also has an effect on these cooperative behaviors.

## Future Directions and Conclusions

These findings illustrate how in-group biases affect affiliative, aggressive, and cooperative behaviors in the animal kingdom. Future research ought to investigate the relevant functions and mechanisms of these biases to better understand the underpinnings of social evolution. As a whole, this research shows how and when in-group bias and various in-group behaviors are exhibited among different animal groups, as they are in humans. Together, these behaviors show the favoritism and benefits extended toward members of one's group; continued exploration will help researchers better understand the effects of these biases and behaviors.

## Inhibition

Victoria L. O'Connor  
Oakland University, Rochester, MI, USA

## Synonyms

[Behavioral control](#); [Impulse control](#); [Self-control](#); [Suppression](#)

## Definition

Inhibition refers to an individual's ability to halt their behavior and control an urge to do something that is tempting; ultimately, suppressing this behavior allows individuals to try a new behavior or response that may be more effective.

## Introduction

Inhibitory mechanisms lie within the frontal lobe of the brain. Impulses can be overridden by higher order control processes when an individual has inhibitory control. Inhibitory control involves an active process in which subjects execute cognitive control over responses, stimuli, and tasks by inhibiting them (Aron 2007).

Inhibitory control has evolved in a variety of species for adaptive responses in different contexts. In humans, inhibition control is defined as an ability to stop an immediate but disadvantageous behavior in exchange for a more favorable one. Human research has focused on two types of inhibition: cognitive and motor. Cognitive inhibition is the ability to regulate actions that are irrelevant to the task at hand. Motor inhibition is the regulation of physical responses or behaviors. Research on motor control has measured inhibition with tasks and questionnaires. Inhibitory control in humans is heritable (Bezdjian et al. 2011) and has been associated with wealth, health, and public safety (Moffitt et al. 2011), addictions (Fillmore and Vogel-Sprott 1999), anxiety and stress (Falconer et al. 2008;

Hardin et al. 2009), obesity (Hofmann et al. 2009), and eating disorders (Jasinska et al. 2012).

Animals have also evolved inhibitory control, but species differences are dependent upon the context. Animals exhibit inhibition towards novelty, food, aggressive behaviors, sexual behaviors, and displays. For example, wolf packs show restraint in pouncing behavior, and in their mating behaviors; the pack works cohesively and at length to hunt together, while also supporting only the alphas in sexual reproduction and offspring rearing. Similarly, frugivorous species must wait until the fruit ripens before eating, while juvenile males in many species must refrain from mating with females with the ominous threat of dominant alphas. In animals, cognitive inhibition is associated with general intelligence (Beran and Hopkins 2018), problem-solving (Müller et al. 2016), behavioral flexibility (Amici et al. 2008), reproductive success (Boogert et al. 2011), cooperation (Burkart and Van Schaik 2010), inequity aversion (Brucks et al. 2017b), persistency, compulsivity, and decision speed (Brucks et al. 2017a).

Overall, the driving forces behind the evolution of cognitive abilities are a mystery. However, previous research has sought to measure cognitive skills in closely related species in an attempt to pin the underlying drivers. Variation in the ecology and sociality between species are separate and predominant theories in cognitive evolution. As such, researchers have found that inhibitory control is more pronounced in social groups (Amici et al. 2008), and has a high prevalence in fission-fusion groups, as opposed to cohesive groups (Aureli et al. 2008). In addition, across species, absolute brain size and dietary breadth predict cognitive performance on inhibitory tasks (MacLean et al. 2014). These studies support both theories; ecology and sociality place pressure on the evolution of cognitive skills, specifically inhibition.

## Examples

Different approaches have sought to measure inhibitory control abilities in a variety of species.

The following tasks have been used in different species to assess inhibition.

**Detour Task.** This task presents an individual with an object that houses a reward. The direct route to the reward is blocked and a longer detour is necessary in order to obtain the reward. There are two types of detour tasks: continuously visible and initially visible. Continuously visible are those in which the reward is always in sight. Initially visible detour tasks are those in which the reward disappears from sight after the initial start. Success at this task exemplifies inhibition; individuals are using their cognitive toolbox to take the less obvious route to retrieve the reward. For example, two groups of sheep were tested on a cylinder task (Knolle et al. 2019). The opaque cylinder is open at the end, and a reward is placed inside. Success occurs when the sheep retrieved the reward at the open end of the cylinder. Failure occurred when the sheep physically touched the clear exterior of the cylinder before retrieving the reward. Sheep performed significantly better than chance, with younger sheep performing the best. This suggests that sheep were able to inhibit their desire to approach the clear barrier, and instead move further to retrieve the reward from the opening (Knolle et al. 2019).

**Delay of Gratification/Impulse Control.** Subjects are presented with a small, immediate food reward. If they take the food reward, the trial is over. If they wait a certain amount of time, they are presented a larger and more enticing food reward. The time delay grows throughout trials to encourage animals to inhibit the urge to take the immediate food reward. This task mimics foraging decision for animals in the wild. Most famously, researchers provided children with a delayed reward task. Children were given the option of taking a smaller, less preferred reward, or waiting for a larger, more valuable reward. When given the opportunity to wait out of sight from the smaller reward, children were able to control their impulse and receive a larger reward (Mischel and Ebbsen 1970).

**Object Displacement.** This test consisted of a presentation of multiple containers. Initially, the containers are empty and visually available to the subjects. Then, the containers are baited in

full view of subjects and closed. Subjects are allowed to select all containers with food, unless they choose an empty container on their first try. Food reward can be moved into different containers, containers can be shifted around after food placement, and containers can vary in physical proximity to subject. Inhibitory control encourages subjects to select only those containers with food, regardless of proximity, or prior trial placement. In a 2001 study by Josep Call, orangutans, chimpanzees, and human children received visible and invisible displacements with species-specific rewards. Across species, subjects were able to correctly select visible displacements, but more likely to select the empty container when it was physically closer, suggesting poor inhibition (Call 2001).

**Object Permanence/A-not-B Task.** This task is based on work by Jean Piaget (1954). A reward is hidden under box “A” for several consecutive trials. The subject forms an association between box “A” and the reward. After several rounds of success, the reward is moved under box “B” in sight of the subject. Inhibitory control encourages the subject to move past the previous association and select box “B” for the reward. Selection of box “A” demonstrates a lack of object permanence. Bray, MacLean, and Hare measured inhibitory control using an A-not-B task in dogs. After observing the food reward moving from “A” to “B,” the dogs were encouraged to inhibit searching in “A” in favor of “B” (Bray et al. 2014). A majority of the dogs were successful in choosing the “B” location, suggesting that they were able to inhibit their urge to attend to “A” (Bray et al. 2014).

**Multiaccess Box.** This box presents multiple solutions to a central reward. Each solution requires a different behavioral repertoire. Initially, the subject is permitted to choose any of the options. Upon success, that solution is then locked. The locking of different solutions encourages innovation and requires inhibition of previously solved, now locked solutions. Auersperg and colleagues developed the multiaccess box, or MAB, to test kea and New Caledonian crows (Auersperg et al. 2011). Both species were able to solve more than one solution,

suggesting the cognitive ability to inhibit extinguished responses (Auersperg et al. 2011).

**Serial-Reversal-Learning.** Subjects are taught to respond to multiple stimuli. When success in response is achieved, the reward contingencies are reversed. So, the reward associated with the first stimuli is now associated with the second stimuli, and vice versa. This alternation can be repeated, and changed from 2-choice discriminations, to multichoice discriminations. In a serial-reversal-learning task of dogs, researchers found that dogs were able to inhibit their learned behavior of the previously rewarded object, and choose the previously unpaired stimuli (Brucks et al. 2017). This suggests that inhibitory control is present and provides an evolutionary advantage in food association and learning (Brucks et al. 2017).

**Social Inhibition.** In a social inhibition task, subjects are taught to differentiate between a generous and a stingy experimenter or conspecific. The generous experimenter always shared the food or reward, whereas the stingy experimenter never shared the food or reward. This experiment could potentially reverse the roles of the stingy and generous experiments. Researchers presented evidence that dogs were able to exhibit inhibitory control as they avoided the stingy experimenter, even when the experimenter held a higher value food (Bray et al. 2014). This presents evidence that inhibitory control is important in social contexts when discriminating between conspecifics, or heterospecifics.

**Stop-Signal Task.** This task was developed in 1984 by Logan and Cowan. It asks the participants to inhibit prepotent responses. The participant initially responds quickly to a predetermined, pretrained stimulus. However, they are also required to stop responding when a stop signal stimulus is displayed. For example, a participant may respond to the stimulus until they observe the stop signal; at this point, all further responding should stop. If they are presented with the stop signal first, they should not respond to the subsequent stimuli. Success is inhibiting the desire to attend to the stimulus after the stop signal display. Honeybees naturally produce stop signals (Nieh 1993). When the

colony's food stores are full of nectar, foraging bees will spend a long time searching for an open storage spot (Nieh 1993). They then begin to tremble dance which signals a stoppage of dancing, reduced recruitment to feeding sites, and increased the colony's nectar intake rate by stimulating bees to function as food-storage bees (Nieh 1993).

**Stroop Task.** This task was first presented in 1935 and measures interference, inhibition, and processing speed (Stroop). This task for humans asks subjects to name the color of the word presented to them. For example, the word green will be printed. In a congruent trial, the word green is the color green, and as such, the subject selects green. In an incongruent trial, the word blue is the color red. To be correct, the subject should select red; failure would be selecting blue. The Stroop effect is the increase in time it takes to inhibit the urge to select blue when the correct answer is red. Response inhibition on this task has been associated with alcohol consumption. More than 500 participants were tested on a Stroop task (Peeters et al. 2015). Their ability to successfully inhibit incorrect responses predicted the initiating of the first drink (Peeters et al. 2015). These results suggest that inhibitory control in humans may predict alcohol use (Peeters et al. 2015).

**Reversed Contingency.** In this task, subjects are given a choice between a smaller quantity, lesser valued food, and a larger quantity, higher valued food. The subjects received the opposite food reward of the one they chose. For example, most subjects would choose the larger quantity, but receive the smaller quantity. In a reversed-contingency task, rhesus macaques were given the option between one and four pieces of food (Murray et al. 2005). All subjects initially selected the larger quantity and received the smaller amount (Murray et al. 2005). However, the monkeys learned to choose the smaller amount, exhibiting inhibitory control and learning of the reversed-contingency task (Murray et al. 2005).

## Conclusion

Challenges in each species' environment encourage the evolution of cognitive mechanisms.

Inhibition is a behavioral skill that is crucial for behavioral flexibility and appropriate decision making. Inhibitory control suggests a high level of cognitive awareness in various species as demonstrated by different tasks. As such, inhibitory control may be context-specific and even vary in individual performances.

## Synonyms

Long-delay conditioning

## Definition

A delay in the peak of a conditioned response (CR) across the duration of a (usually) long conditioned stimulus (CS).

## Introduction

In the classical conditioning paradigm, presentation of a stimulus (e.g., a tone) is paired with presentation of an unconditioned stimulus (US, e.g., food). These pairings usually result in the stimulus coming to elicit a response (e.g., salivation); that is, the previously neutral stimulus becomes a conditioned stimulus (CS) which can elicit a conditioned response (CR). In the most common arrangement, known as *delay conditioning*, the CS onset occurs shortly before US delivery, and the CR develops as

an anticipatory response triggered by the CS in preparation for the US. In general, one may assume that subjects come to respond to the CS as a unitary event; however, if the CS has a long duration, the CR onset may be delayed, peaking during the temporal segments of the CS presentation that are most contiguous with the US. Thus, rather than eliciting a response through its entire duration, the CS elicits little to no responding during its initial segments and robust responding during its final segments (a “segment” is any portion or subunit of the stimulus unit, defined by its temporal characteristics; see Fig. 1). Because this procedure is a variation of the commonly used delay conditioning procedure, with exception of the longer duration CS, inhibition of delay is also known as *long-delay conditioning*.

Pavlov (1927) described several studies in which a long CS produced a pattern of response with the CR developing progressively, being unobservable during the initial presentation of the CS and gradually increasing as time of US delivery approached. Figure 1 presents a graphic representation of the inhibition of delay (long-delay conditioning) procedure and some of its primary characteristics, which will be discussed in subsequent sections.

Characteristics and Parameters

Inhibition of delay has three primary characteristics: (1) a progressive reduction in the CR elicited by the early portion of the CS, (2) a CR that is progressively confined to the later portion of the CS, and (3) the capacity of the early segment of the CS to attenuate the CR that another stimulus would otherwise elicit (Rescorla 1967). Inhibition of delay has been reported in a variety of species including cats (e.g., Oleson et al. 1973), dogs (e.g., Pavlov 1927; Rescorla 1967), rabbits (e.g., Vogel 2012), and rats (e.g., Brush and Gendron 1998; Escobar et al. 2015; Schachtman et al. 1987), using a variety of stimuli, including auditory, visual, and tactile with a variety of durations (see Pavlov 1927, for a review). Late peaks of CR occur when the US is an appetitive event such as food (e.g., Pavlov 1927) or sugar (e.g., Escobar et al. 2015) or when the US is an aversive event such as a shock (e.g., Rescorla 1967; Vogel 2012). Finally, inhibition of delay can be observed in multiple response systems, including the salivation reflex (Pavlov 1927), goal-tracking responses (Escobar et al. 2015), avoidance responses (Rescorla 1967), the pupillary reflex (Oleson et al. 1973), conditioned freezing (Schachtman et al. 1987), and the blinking reflex (Vogel 2012).

**Inhibition of Delay, Fig. 1** Comparison of the typical delay and long-delay conditioning procedures. *Arrows* represent the time line, *gray boxes* above the time line represent CS presentation, and *black marks* under the time line represent US delivery. Early in training, both short and long CSs produce CRs (*dotted gray line*) that are elicited through the duration of the CS and for a time period following CS termination. Later in training,

however, CR elicitation in the long CS is no longer evident in its initial segment (*i*), starting late and peaking during its final segment (*f*). Likely because of the close proximity and overlap of the initial and final segments of the short CS, the peak of the CR changes little throughout training. The shift of the peak of the CR toward the final segment of the long-delay CS reflects the occurrence of inhibition of delay

## What Is Learned During Inhibition of Delay?

Pavlov (1927) described conditioning through the duration of a long-delay CS as having two phases. During the initial phase, the *inactivity phase*, little responding should be observed; in contrast, during the final *activity phase*, robust responding should be observed. The transition between the inactivity and activity phases was not abrupt; the CR would increase in strength gradually until peaking during the final, activity, phase. Based on these observations, Pavlov suggested two possible explanations for the observed lack of responding during the inactivity phase. First, during the initial phase, the strength of the CR could be accumulating or summing, such that when it reaches enough strength, it is finally elicited. He rejected this possibility because if the same stimulus is used, but with a shorter duration, the CR is robust and occurs almost simultaneously with the presentation of the CS (it would be unlikely that simply by extending the CS duration, a different summation rule would need to apply to elicit a CR). Second, an antagonistic (i.e., opposite) process could be operating during the initial phase, such that any CR that could be potentially elicited by the CS is overcome by it. The candidate process would be *inhibition*, a type of learning in which the presence of the CS comes to predict the absence of an otherwise expected US. Pavlov's observations led to the conclusion that the long delay resulted in *internal inhibition* processes that mask the CR. He supported this view with multiple observations. First, presentation of an irrelevant stimulus disrupted the inactivity phase and "unmasked" the CR. This is known as *external disinhibition*, the observation that a stimulus external to the situation can disrupt the inhibitory process that masks the response. Second, if a short CS that elicited a strong CR was presented during the initial phase of the long-delay CS, responding to the short CS was attenuated. This is known as *negative summation* and reflects the observation that a stimulus that has acquired inhibitory properties can transfer those properties to other stimuli that elicit CRs (known as *excitatory stimuli*).

Rescorla (1967) trained dogs to perform an avoidance task, in which presentation of a long CS was followed by delivery of a foot shock (US) to one of the compartments of a shuttle box. The dogs could escape the US by jumping over a barrier that separated the shock compartment from a "safe" compartment. The dogs could avoid the shock by jumping over the barrier immediately following the CS onset. Rescorla observed that the dogs produced the avoidance response late in the CS presentation, and the initial phase of the CS attenuated the fear responses otherwise exhibited by the dogs when placed in the shuttle box (i.e., negative summation). Thus, Rescorla's studies supported Pavlov's view that long-delay conditioning resulted in a form of inhibitory learning, *inhibition of delay*. A problem with this interpretation is that *inhibitory conditioning* is a process that cannot be easily measured directly (e.g., if a dog does not salivate when presented with a sound, is it because conditioning has not occurred or because an inhibitory process has developed?).

The standard assessment of conditioned inhibition involves the concurrent use of two indirect tests: the *negative summation test* which, as described above, involves determining whether the inhibitor can prevent the response otherwise produced by an excitor, and the *retardation test* which assesses the rate of acquisition of the CR to a potential inhibitor. A potential problem with the summation test is that decreased CR to the excitor could be explained in terms of the inhibitor capturing the animal's attention. A potential problem with the retardation test is that slow rates of acquisition could be explained in terms of the inhibitor being ignored by the subject. Rescorla (1969) suggested that each test could be used to control for the other's alternative explanation if used in conjunction: A stimulus that commands increased attention cannot be ignored. Because animals cannot attend and ignore a stimulus at the same time, the use of both tests (the *two-test strategy*) has become the standard procedure to assess whether a stimulus is inhibitory. Escobar et al. (2015) used the two-test strategy in a study in which rats experienced a long CS that predicted sugar pellet delivery. When the peak of the CR was firmly

established in the final portion of the CS, either a second CS that predicted sugar delivery in its initial portion was presented together with the long-delay CS (summation test) or pellets were delivered during the initial portion of the long-delay CS to assess the development of an excitatory response (retardation test). The initial portion of the CS was slow in becoming excitatory (i.e., retardation), but it failed to attenuate the CR produced by the second CS (i.e., no summation). Thus, long-delay CSs can exhibit inhibitory properties during their initial segment as assessed with either a summation or a retardation test but, to date, no study has demonstrated such inhibitory properties within a single preparation.

Despite these seemingly conflicting results, Pavlov's (cf. 1927) explanation continues to be the most accepted view of inhibition of delay: Excitation (response production) develops early to the entire CS duration, but inhibition (response suppression) develops over training to the portion of the CS that is more distal from the US, eventually overcoming excitation (see Fig. 1). Vogel (2012) assessed this possibility by training rabbits in a preparation in which a long-delay CS signaled the presentation of a mild shock US delivered to the subjects' eyelid. As training progressed, rabbits began to blink in anticipation of the US, and this blinking became confined to the later portion of the CS (i.e., inhibition of delay). Presentation of a novel stimulus immediately prior to CS onset changed the peak of the CR to an earlier portion of the CS, suggesting some "hidden" excitation in the early portion of the CS, which was unmasked by the novel stimulus.

## Theoretical Explanations of Inhibition of Delay

The main challenge to providing a theoretical explanation of inhibition of delay is that CSs are typically regarded as unitary entities that acquire a value as predictors of the US. However, although parsimonious, this perspective ignores the fact that organisms learn not only about the physical properties of a stimulus but also about the temporal characteristics that define that stimulus

(e.g., Arcediano and Miller 2002). Indeed, different portions of a stimulus have different characteristics. For example, the onset of a stimulus is accompanied by a state change in which the absent stimulus is now present, whereas the termination of a stimulus is accompanied by a state change in which the present stimulus becomes absent. The duration of a stimulus also has temporal characteristics (e.g., each instant occurs a given time after onset and a given time before termination). So-called *real-time theories* assume that learning is a continuous event in which each instant of an experience is a stimulus element that develops associations to other elements of the same stimulus and to elements of other stimuli experienced in close proximity; the pattern of activation resulting from all components of that experience is what determines the response. For example, Vogel et al. (2003) suggested that elements sampled during the final portion of the stimulus are very likely to be sampled together with elements of the US, whereas elements sampled during the initial portion of the stimulus are less likely to be sampled together with elements of the US. Thus, elements from the final portion of the stimulus will develop strong excitatory associations with the US. In contrast, elements from the initial portion of the stimulus will eventually develop inhibitory associations to the US because they are more often sampled apart than together. By viewing each stimulus as a collection of elements rather than a unitary event, componential models can easily accommodate the temporal displacement of the CR that is the hallmark of inhibition of delay.

## Conclusion

Inhibition of delay (long-delay conditioning) is a robust phenomenon that has been reported with a variety of species, stimuli, stimulus durations, and response systems. The behavioral characteristics of the phenomenon (a CR that progressively decreases in the initial segment of a long CS and peaks in the later segments of the CS) are well defined, but exactly why this pattern of behavior emerges is not clear. The most accepted view is

that the CS is initially excitatory but, with progressive training, the distal (initial) segment of the CS becomes inhibitory and this inhibitory process eventually overcomes the previously acquired excitation. Whether this inhibitory process is of the same nature as other forms of conditioned inhibition is still debated. However, it is clear that the phenomenon is consistent with the view that CSs are not unitary events and that the temporal characteristics of a CS can be as powerful determinants of the response it elicits as are its physical characteristics.

## Definition

Innate behaviors are those behaviors that are genetically hardwired in an organism's behavioral repertoire. They are performed in response to very specific, environmental stimulation. They include reflexes, fixed or modal action patterns, taxis, and kinesis.

Behavior is classified into two broad, mutually exclusive categories: innate behaviors and instrumental (aka voluntary) behaviors. Innate behaviors are genetically determined and linked to a specific releaser stimulus in the environment. Most have apparent survival value and may even appear in neonates or the very young, while others may not appear until sexual maturity.

## Reflexes

Reflexes are observed in both human and non-human animals. They are involuntary, nearly

instantaneous responses to specific environmental stimuli called releaser stimuli. There are dozens of reflexes across species. In humans (and many other vertebrates), common examples include shivering, sneezing, coughing, and the startle response. Newborn humans have several primitive reflexes, such as rooting, sucking, and the palmar grasping reflex; some of these primitive reflexes disappear as the infant matures.

**Releaser stimuli.** All reflexes (and other innate behaviors) are elicited by very specific stimuli called releaser stimuli or sign stimuli. A releaser stimulus is defined as a feature of a more complex stimulus array that will provoke the reflex. For example, food caught in your throat that irritates the trachea elicits coughing; a tap on the patellar tendon causes a knee jerk, and light shined in the eye causes pupil constriction. There tends to be a direct, hard-wired relationship between a releaser stimulus and its corresponding reflex that is often mediated via the reflex arc.

The reflex arc is a neural pathway that controls reflexes (see Fig. 1). There are two types of reflex

arcs. The *autonomic reflex arc* is a chemically mediated process that regulates organ systems by maintaining homeostasis between the sympathetic and parasympathetic nervous system. It regulates systems like the heart, the lungs, and the digestive tract using smooth muscles. The *somatic reflex arc* controls bodily responses like the patellar reflex, or knee jerk, and the heat/pain withdrawal reflex. For a detailed biological explanation of autonomic and somatic reflex arcs, see Biga et al. (2018).

In most vertebrates, the *somatic reflex* does not require cerebral control of the circuit. Reflexive synapses occur in the peripheral nervous system (PNS), although additional signals to the brain via the central nervous system (CNS) do make us aware of the stimulus and the response. However, bypassing cerebral involvement allows for very fast responding. The speed of the reflex arc causes the analysis and awareness of the reflexive behavior to occur after the response has already occurred.

**The Somatic Reflex Arc.** Environmental stimulation is detected in the skin by sensory neurons,

**Innate Behaviors, Fig. 1** The reflex is mediated by the reflex arc. Environmental stimulation is detected by sensory neurons, called afferent neurons, which propagate a neural signal to the spinal cord. Inside the spinal cord, the afferent neuron the motor neuron, called the efferent

neuron. The motor neuron sends a signal to the muscles which contract and cause movement. Note that there is no required cerebral involvement. (Source: Wikimedia Commons. Reflex arc, Wikimedia commons. [https://commons.wikimedia.org/wiki/File:Img\\_arc\\_reflex\\_muda.svg](https://commons.wikimedia.org/wiki/File:Img_arc_reflex_muda.svg))

called *afferent neurons* that propagate neural signals to the *posterior horn* of the spinal cord (or to the brain stem). Inside the spinal cord, the afferent neuron stimulates an *interneuron* that in turn stimulates the motor neuron, called the *efferent neuron*. The motor neuron sends a signal from the *anterior horn* to the muscles that, in turn, cause the reflexive movement.

**Reflexes and Invertebrates.** Reflexes that are mitigated by the reflex arc, by definition, occur in most vertebrate animals, including mammals, birds, reptiles, bony and cartilaginous fishes, and amphibians. But some simple reflexes, such as limb or gill retraction in response to touch, or electrical stimulation have been shown to occur in certain invertebrates such as stickbugs (Bassler 1992), locusts (Seigler and Burrows 1986), aplysia (Cleary et al. 1995), and crayfish (Skorupski 1992). Watanabe and Mizunami (2007) demonstrated conditioning of the salivation reflex in cockroaches, using a procedure that mimicked Ivan Pavlov's early classical conditioning work with dogs. However, in the recent study, the dependent variable was the reflexive neural firing rate of the salivary neuron instead of a direct assessment of salivation. This was the first study to demonstrate conditioned salivation in insects.

## History of the Reflex

René Descartes, a French philosopher, scientist, and mathematician in the seventeenth century (see Fig. 2), first described *reflexes* as responses that reflected the stimuli that produced them. In his, *Discourse on the Method* (1637), Descartes suggested that the behavior of animals was purely mechanical. He was the first to propose the mechanisms that govern reflexes.

According to Descartes, some responses were initiated by stimuli in the physical world while others were initiated in the mind. He argued that animals and humans shared the involuntary, stimulus-based behaviors that he called *reflexes*. His explanation of the underlying mechanism of these responses was based on a simple sensory input/motor output system controlled by the environment, nerves, the brain, and the mind. *Animal*
